Since the first observation of the $\Lambda_c^+ \rightarrow \Lambda e^+\nu_e$ decay, the lightest baryon containing a charm quark, in 1979 [1], its hadronic decays have been studied extensively. However, information about semileptonic decays of the $\Lambda_c^+$ baryon is sparse [2–6]. The measurement of the branching fraction of $\Lambda_c^+ \rightarrow \Lambda l^+\nu_l$ ($l = e, \mu$) was first performed by the ARGUS collaboration [3] and then by the CLEO collaboration [4] before 1994. Recently, the BESIII collaboration measured the absolute branching fraction of $\Lambda_c^+ \rightarrow \Lambda e^+\nu_e$ and $\Lambda_c^+ \rightarrow \Lambda l^+\nu_l$ to be $(3.63 \pm 0.43)\%$ [5] and $(3.49 \pm 0.53)\%$ [6], respectively. A comparison of the exclusive semileptonic decay branching fraction $B(\Lambda_c^+ \rightarrow \Lambda e^+\nu_e)$ and the inclusive semileptonic decay branching fraction $B(\Lambda_c^+ \rightarrow X e^+\nu_e)$, where $X$ refers to any possible particle system, will guide searches for new semileptonic decay modes. In addition, using the known $\Lambda_c^+$ lifetime, the semileptonic decay width $\Gamma(\Lambda_c^+ \rightarrow X e^+\nu_e)$ can be determined. Comparing $\Gamma(\Lambda_c^+ \rightarrow X e^+\nu_e)$ with the charge-averaged nonstrange $D$ semileptonic decay width $\bar{\Gamma}(D \rightarrow X e^+\nu_e)$, the ratio $\left[ \Gamma(\Lambda_c^+ \rightarrow X e^+\nu_e) / \bar{\Gamma}(D \rightarrow X e^+\nu_e) \right]$ can be obtained. This ratio is predicted to be $1.67$ [8,9] using an effective-quark theory calculation and about 1.2 based on a calculation using the heavy-quark expansion [10]. Therefore, a more precise measurement of $B(\Lambda_c^+ \rightarrow X e^+\nu_e)$ is desirable to test these theoretical predictions.

Measurement of $B(\Lambda_c^+ \rightarrow X e^+\nu_e)$ was only performed by the MARK II collaboration in 1982, with a result of $(4.5 \pm 1.7)\%$ [11] using an $e^+e^-$ collision data sample taken at center-of-mass energies from 4.5 to 6.8 GeV. The determination of $B(\Lambda_c^+ \rightarrow X e^+\nu_e)$ is obtained from signal events containing $\Lambda e^+ (p e^+)$ [12], with the observed $\Lambda(\bar{p})$ serving as a tag for a charmed baryon event. All these events are assumed to be from charmed baryon pair production and subsequent $\Lambda_c^+$ semileptonic decay. This assumption should be questioned as there are $e^+e^- \rightarrow c\bar{c} \rightarrow D \bar{D} \Lambda_c^+\Lambda_c^- X$ continuum events [13]. Besides, they need to estimate the total number of produced charmed baryon events, which has large uncertainties and is model dependent [1]. In this Letter, we present the first absolute measurement of $B(\Lambda_c^+ \rightarrow X e^+\nu_e)$ by employing a double-tag technique [14]. This technique takes advantage of a clean $\Lambda_c^+\bar{\Lambda}_c^-$ sample just above the threshold and, thus, obviates the need to make the above assumption or estimate the total number of produced charmed baryon events.

Our measurement is performed by analyzing an $e^+e^-$ collision data sample of 567 pb$^{-1}$ accumulated at $\sqrt{s} = 4.6$ GeV and recorded with the BESIII detector [15] at the Beijing Electron-Positron Collider II (BEPCII) [16]. A detailed description of the BESIII detector can be found in Ref. [15].

A GEANT4-based [17] Monte Carlo (MC) simulation is used to estimate the signal efficiency, optimize the selection criteria, and understand the backgrounds. In the simulation, the effects of beam-energy spread and initial state radiation (ISR) are incorporated using KKMC [18], and the final-state...
radiation (FSR) is modeled by PHOTOS [19]. A MC sample consisting of $\Lambda_c^+\Lambda_c^-$ pairs, $D_s^{(*)}\bar D_s^{(*)}$ pairs, ISR to low-mass charmonium ($\psi$) states, and continuum processes incorporates most expected channels. The known decay modes are modeled with EVTGEN [20,21] using branching fractions taken from the Particle Data Group (PDG) [7], and the remaining unknown decays from the charmonium states with LUNDCHARM [22].

A double-tag technique, first developed by the MARK III collaboration [23], is employed. First, we fully reconstruct one $\Lambda_c^-$ and, then, search for candidates of the signal decay in the rest of the event that is recoiling against the tagged $\Lambda_c^-$. Hence, the absolute branching fraction of the inclusive semileptonic decay can be measured without knowing the total number of $\Lambda_c^+\Lambda_c^-$ pairs produced, thus, eliminating the related systematic uncertainty. The tag candidates are reconstructed through the decays $\Lambda_c^- \rightarrow \bar p K_S^0$ and $\bar p K_S^0 \rightarrow \bar p K^+\pi^-$, which have large branching fractions and low backgrounds.

The charged tracks, except those from $K_S^0$, are required to have a polar angle $\theta$ with respect to the beam direction within the multilayer drift chamber (MDC) acceptance $|\cos \theta| < 0.93$, and a distance of closest approach to the interaction point (IP) within 10 cm along the beam direction and 1 cm in the plane transverse to the beam direction. Particle identification (PID) for charged pions, kaons, and protons is performed by exploiting time-of-flight (TOF) information and specific ionization energy loss $dE/dx$ measured by the MDC. The confidence level (C.L.) under each particle hypothesis ($p$, $K$, or $\pi$) is calculated; each charged track is assigned the particle type with the largest PID C. L. The $K_S^0$ meson candidates are reconstructed from two oppositely charged tracks to which no PID criteria are applied and which are assigned the pion mass hypothesis. The charged tracks from the $K_S^0$ candidate must satisfy $|\cos \theta| < 0.93$. Furthermore, due to the long lifetime of the $K_S^0$ meson, there is a less stringent criterion on the distance of closest approach to the IP in the beam direction of less than 20 cm, and there is no requirement on the distance of closest approach in the plane transverse to the beam direction. The invariant mass of the track pair is required to be in the range (0.487, 0.511) GeV/$c^2$. Furthermore, the $\pi^+\pi^-$ pair is constrained to be consistent with originating from a common decay vertex by means of a vertex fit. In addition, the decay length, which is the distance between the IP and the decay vertex, is required to be larger than twice its resolution.

To suppress combinatorial backgrounds, two kinematic variables are used to select the tag candidates. These are the energy difference $\Delta E = E_{\bar p\Lambda_c^-} - E_{\text{beam}}$ and the beam-constrained (BC) mass $M_{\text{BC}} = \sqrt{E_{\text{beam}}^2 / c^4 - |\vec p_{\bar p\Lambda_c^-}|^2 / c^2}$, where $E_{\text{beam}}$ is the beam energy, $E_{\bar p\Lambda_c^-}$ and $|\vec p_{\bar p\Lambda_c^-}|$ are the reconstructed energy and three momentum of the tag candidate in the rest frame of the $e^+e^-$ system, respectively. We require $\Delta E$ to be within $(-3\sigma, 3\sigma)$ of the peak of the $\Delta E$ distribution, where $\sigma$ is the resolution of the $\Delta E$ distribution. Table I gives the $\Delta E$ requirements for each tag mode. If there are multiple candidates for the same tag mode in a given event, only the combination with the smallest $|\Delta E|$ is retained for further analysis. To determine the tag yields, we apply a fit to the $M_{\text{BC}}$ distributions, as shown in Fig. 1. In the fits, the signal shape is modeled by the shape derived from MC simulation convolved with a Gaussian function that describes the resolution difference between data and MC simulation; the combinatorial background is described by an ARGUS function [24]. We obtain the tag yields by subtracting the integral of the background function in the signal region 2.282 < $M_{\text{BC}}$ < 2.300 GeV/$c^2$ from the total number of events in the same region. The tails of the $M_{\text{BC}}$ distribution above the nominal $\Lambda_c^-$ mass are due to the effects of ISR and FSR. The tag yields and the corresponding detection efficiencies are summarized in Table I.

In the selected tag sample of $\bar p\Lambda_c^-$ candidates, we search for charged tracks consistent with being an electron or positron. To ensure that the charged tracks originate from the IP, the same distance of closest approach selection criteria are used as for the non-$K_S^0$ daughters of the tag candidates. The track is required to satisfy $|\cos \theta| < 0.8$ to ensure that it lies within the acceptance of the barrel of the electromagnetic calorimeter (EMC), which has better energy resolution than the EMC end caps. The momentum of the charged track is required to be greater than 200 MeV/$c$, as it is difficult to separate positrons from other particles with low momenta. The selected tracks are divided into right-sign and wrong-sign samples, where the

**FIG. 1.** $M_{\text{BC}}$ distributions for the different tag modes in data. The solid blue line is the total fit, the dashed red line is the background component, and the pink arrows denote the $M_{\text{BC}}$ signal region.
charge of the right-sign (wrong-sign) track is required to be opposite (equal) to that of the tag candidate.

The PID of the selected tracks is implemented with the information of the $dE/dx$, TOF and EMC, and the C.L. under each particle hypothesis ($e$, $\pi$, $K$, or $p$) is calculated. Positron candidates must satisfy C.L.($e$) > 0.001 and C.L.($e$)/[C.L.$(e)$ + C.L.$(\pi)$ + C.L.$(K)$ + C.L.$(p)$] > 0.8.

To further suppress the backgrounds from charged pions, $E_e/p_e > 0.8$ is required, where $E_e$ and $p_e$ are the deposited energy in the EMC and momentum measured by the MDC, respectively. The remaining selected charged tracks are assigned the hadron type corresponding to the highest C.L. that is greater than 0.001. The track is rejected if it does not have a C.L. greater than 0.001 for any hypothesis.

The identified positron sample contains sizable backgrounds from misidentified hadrons. To evaluate these backgrounds, knowledge of their yields and corresponding misidentification probabilities is required. The real right-sign and wrong-sign positron yields are determined individually by unfolding the matrix [25–27]

\[
\begin{pmatrix}
N_{e}^{\text{obs}} \\
N_{\pi}^{\text{obs}} \\
N_{K}^{\text{obs}} \\
N_{p}^{\text{obs}}
\end{pmatrix}
= 
\begin{pmatrix}
P_{e\rightarrow e} & P_{\pi\rightarrow e} & P_{K\rightarrow e} & P_{p\rightarrow e} \\
P_{e\rightarrow \pi} & P_{\pi\rightarrow \pi} & P_{K\rightarrow \pi} & P_{p\rightarrow \pi} \\
P_{e\rightarrow K} & P_{\pi\rightarrow K} & P_{K\rightarrow K} & P_{p\rightarrow K} \\
P_{e\rightarrow p} & P_{\pi\rightarrow p} & P_{K\rightarrow p} & P_{p\rightarrow p}
\end{pmatrix}
\begin{pmatrix}
N_{e}^{\text{true}} \\
N_{\pi}^{\text{true}} \\
N_{K}^{\text{true}} \\
N_{p}^{\text{true}}
\end{pmatrix},
\]

where $N_{a}^{\text{obs}}$ is the observed yield of particle species $a$ ($a$ denotes $e$, $\pi$, $K$, or $p$), $P_{a\rightarrow b}$ is the probability of identifying particle $a$ as particle $b$, and $N_{a}^{\text{true}}$ is the true yield of particle $a$ in the studied sample. The elements of the PID efficiency matrix $P_{a\rightarrow b}$ are obtained by studying corresponding control samples selected from data. The charged pion and proton samples are selected from $J/\psi \rightarrow p\bar{p}\pi^{+}\pi^{-}$ events. The charged kaon and positron samples are selected from $J/\psi \rightarrow K^{+}K^{-}K^{+}K^{-}$ and radiative Bhabha events, respectively. Because of the different event topologies, the PID efficiency of positrons from $\Lambda_{c}^{+}$ decays, and secondary positrons, not directly arising from $\Lambda_{c}^{+}$ decays and originating predominantly from $\gamma$ conversions and $\pi^{0}$ Dalitz decays.

Detailed MC studies indicate that the secondary positrons are charge symmetric; hence, their yield can be evaluated from the wrong-sign positron sample and subtracted from the total right-sign positron yields. The reliability of the wrong-sign subtraction has been validated by MC studies.

The tracking efficiency in a given momentum interval, including geometrical acceptance (80% due to the cut of $|\cos \theta| < 0.8$), track reconstruction efficiency, selection efficiency, and resolution effects, is corrected by unfolding the following matrix equation:

\[
N_{j}^{\text{true}} = \sum_{j} T(i|j)N_{j}^{\text{pro}}.
\]

where the tracking efficiency matrix $T(i|j)$ describes the probability of positrons produced in the $j$th momentum interval to be reconstructed in the $i$th momentum interval, $N_{j}^{\text{pro}}$ is the number of primary positrons produced in the $j$th momentum interval, and $N_{j}^{\text{true}}$ is the true yield of positron reconstructed in the $i$th momentum interval. The tracking efficiency matrix is obtained by studying the positron MC sample selected from $\Lambda_{c}^{+}$ semileptonic events. After this procedure is applied, we obtain the efficiency-corrected positron momentum spectrum above 200 MeV/c in the laboratory frame. Table II summarizes the positron yields obtained after each correction step.

The fraction of positrons below 200 MeV/c is obtained by fitting the efficiency-corrected positron momentum spectrum.
spectrum with the sum of the spectra of the exclusive decay channels (Table III), as shown in Fig. 3. In the fit, the branching fraction of each component is allowed to vary within the given uncertainty. From the fit, we obtain the fraction of positrons below 200 MeV/c to be (5.6±1.5)%, where the uncertainty is systematic derived from variations of the fit assumptions. The branching fraction of the inclusive semileptonic decay of the \( \Lambda_c^+ \) baryon is then calculated with

\[
B(\Lambda_c^+ \to X e^+ \nu_e) = \frac{N_{\text{pos}}(p_e > 200 \text{ MeV/c})}{N_{\text{tag}}[1 - f(p_e < 200 \text{ MeV/c})]},
\]

where \( N_{\text{pos}}(p_e > 200 \text{ MeV/c}) \) is the yield of positrons with momentum \( p_e \) above 200 MeV/c after the correction of the tracking efficiency, \( N_{\text{tag}} \) is the tag yield, and \( f(p_e < 200 \text{ MeV/c}) \) is the fraction of positrons below 200 MeV/c. Finally, we obtain \( B(\Lambda_c^+ \to X e^+ \nu_e) = (3.95 \pm 0.34)\% \), where the uncertainty is statistical only.

The systematic uncertainties in this analysis are listed in Table IV. The tag yield systematic uncertainty is estimated to be 1.0% by using alternative fits to the \( M_{BC} \) distribution with different signal shapes, background parameters, and fitting ranges. The systematic uncertainty related to the tracking efficiency is estimated to be 1.0% by studying radiative Bhabha scattering events [5]. The systematic uncertainty in the positron identification efficiency is estimated by comparing the positron PID efficiencies in different MC simulated semileptonic \( \Lambda_c^+ \) decays. The largest relative difference of the positron PID efficiency is assigned as the systematic uncertainty. The uncertainties in the other elements of the PID efficiency matrix are estimated by comparing the matrix elements obtained from \( \Lambda_c^+ \bar{\Lambda}_c^- \) pair MC samples with those obtained from MC samples of radiative Bhabha events, \( J/\psi \to p \bar{p} \pi^+ \pi^- \) and \( J/\psi \to K^+ K^- K^+ K^- \) MC samples. Adding them in quadrature, we assign 0.9% as the systematic uncertainty related to PID. The uncertainty associated with the \( M_{BC} \) sideband subtraction is estimated to be 0.5% by using an alternative \( M_{BC} \) sideband region. To estimate the uncertainty in the extrapolation of the positron momentum spectrum, we perform an alternative fit in which the branching fraction of each fit component is unconstrained. In addition, we use an alternative form-factor model and repeat the fit. Adding these effects in quadrature, we attribute 1.5% as the systematic uncertainty related to the extrapolation procedure. The uncertainty due to limited statistics of data and MC simulation used to determine the PID efficiency matrix and tracking efficiency matrix is estimated by repeating the PID unfolding procedure and correction of tracking.

TABLE II. Positron yields in data after each procedure. The uncertainties are statistical.

efficiency. In each repetition, we vary each element of the PID efficiency matrix and tracking efficiency matrix within the corresponding error simultaneously. The corresponding systematic uncertainty is derived from 10 000 independent repetitions and is estimated to be 0.4%. Adding all uncertainties in quadrature, the total systematic uncertainty is determined to be 2.3%.

The absolute branching fraction of the inclusive semileptonic decays of the $\Lambda_{c}^{+}$ baryon is determined to be $B(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e}) = (3.95 \pm 0.34 \pm 0.09)\%$, where the first and second uncertainties are statistical and systematic, respectively. Compared with the branching fraction of $\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e}$ measured by the BESIII collaboration [5], the ratio $[B(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e})]/[B(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e})]$ is determined to be $91.9 \pm 12.5 \pm 5.4\%$, where the systematic uncertainty related to the tracking efficiency of the positron cancels. Using the known $\Lambda_{c}^{+}$ lifetime [7], we obtain the semileptonic decay width $\Gamma(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e}) = (1.98 \pm 0.18) \times 10^{11}$ s$^{-1}$. Comparing this with the charge-averaged semileptonic decay width of nonstrange charmed mesons $\Gamma(D \rightarrow X e^{+} \nu_{e})$ [7], the ratio $[\Gamma(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e})]/\Gamma(D \rightarrow X e^{+} \nu_{e})$ is determined to be $1.26 \pm 0.12$. A comparison of the branching fraction and ratio of the semileptonic decay width between experimental measurements and theoretical predictions can be found in Table V.

In summary, by analyzing a data sample corresponding to an integrated luminosity of 567 pb$^{-1}$ taken at a center-of-mass energy $\sqrt{s} = 4.6$ GeV, we report the absolute measurement of the inclusive semileptonic $\Lambda_{c}^{+}$ decay branching fraction $B(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e}) = (3.95 \pm 0.34 \pm 0.09)\%$. The uncertainty is reduced by a factor of 4 compared to the MARK II result [11]. Based on the BESIII measurements [5], we obtain the ratio of the branching fraction to be $[B(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e})]/[B(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e})] = (91.9 \pm 12.5 \pm 5.4)\%$. We also determine the ratio $[\Gamma(\Lambda_{c}^{+} \rightarrow X e^{+} \nu_{e})]/\Gamma(D \rightarrow X e^{+} \nu_{e})] = 1.26 \pm 0.12$, which restricts different models as given in Table V.

The BESIII collaboration thanks the staff of BEPCII and the IHEP computing center for their strong support. This work is supported in part by the National Key Basic Research Program of China under Contract No. 2015CBB56700; the National Natural Science Foundation of China (NSFC) under Contracts No. 11235011, No. 11335008, No. 11425524, No. 11625523, and No. 11635010; the Chinese Academy of Sciences (CAS) Large-Scale Scientific Facility Program; the CAS Center for Excellence in Particle Physics (CCEPP); Joint Large-Scale Scientific Facility Funds of the NSFC and CAS under Contracts No. U1332201, No. U1532257, and No. U1532258; CAS under Contracts No. KJCX2-YW-N29 and No. KJCX2-YW-N45; CAS Key Research Program of Frontier Sciences under Contracts No. QYZDJ-SSW-SLH003 and No. QYZDJ-SSW-SLH040; 100 Talents Program of CAS; National 1000 Talents Program of China; INPAC and Shanghai Key Laboratory for Particle Physics and Cosmology; German Research Foundation DFG under Contracts No. Collaborative Research Center CRC 1044 and No. FOR 2359; Istituto Nazionale di Fisica Nucleare, Italy; Koninklijke Nederlandse Akademie van Wetenschappen (KNAW) under Contract No. 530-4CDP03; Ministry of Development of Turkey under Contract No. DPT2006K-120470; National Science and Technology Fund; The Swedish Research Council; U.S. Department of Energy under Contracts No. DE-FG02-05ER41374, No. DE-SC-0010118, No. DE-SC-0010504 and No. DE-SC-0012069; University of Groningen (RuG) and the Helmholtzzentrum fuer Schwerionenforschung GmbH (GSI), Darmstadt; WCU Program of National Research Foundation of Korea under Contract No. R32-2008-000-10155-0.
