Title: Economic Development and CO<sub>2</sub> emissions

Authors: Rasmus Augustsson and Robin Abrahamsson

Tutor: Anna Nordén

Date: May 2020

Key terms: Environmental Kuznets Curve, Carbon dioxide, Middle-income countries, High-income countries, Economic Development

---

## Abstract

The purpose of this paper is to investigate the relationship between economic development and pollution in the middle- and high-income countries for the period between 1960 and 2014. The study is conducted by first testing the environmental Kuznets curve, an economic theory that income has an inverted U-shape relationship with environmental degradation. Later, the Revised environmental Kuznets curve is tested, an economic theory that countries undergoing economic development at a later period will have a lower peak of environmental degradation compared to countries undergoing economic development at an earlier period. Empirical tests of carbon dioxide (CO<sub>2</sub>) per capita and income (GDP per capita) were conducted in two different panel tests containing middle-income countries in one and high-income countries in the other. The observed relationship shows that a country's early economic development degrades the environment until what is called the turning point is reached, after which the environment improves with further economic development. Thus, the expected inverted U-shape is observed for both middle-income countries and high-income countries. Furthermore, the tests tell us that the turning point for middle-income countries is significantly lower than for high-income countries, which is the expected result.

## 1. Introduction

---

*The purpose of this part is to introduce the reader to what will be covered in the chapter. This is presented at the start of each chapter and is adapted to reflect the content of the chapter.*

---

Middle-income countries (MICs) have the most substantial proportion of the world's carbon dioxide emissions (Alonso, Glennie & Sumner, 2014). The transformation of rainforests to agriculture, most occurring in MICs, is considered to be one of the largest sources to the rising carbon dioxide pollution (Osborne & Kiker, 2005). The MICs are home to 75% of the world's population (World Bank, 2019), and on average, have the world's fastest economic growth. Which transformation is in line with the logic of the *Environmental Kuznets Curve* (EKC). In the earlier stages of economic development, the priority is production, and people are interested in jobs, rather than less pollution and a clean environment (Dasgupta et al., 2002).

The World Bank has divided countries into four different stages, low-income, low, middle-income, upper-middle-income, and high-income countries. In this study, the focus is on low-middle income, and upper-middle-income merged to just middle-income countries and high-income countries. The already developed high-income countries made a large part of their economic growth without thinking about the environmental impact, that middle- and low-income countries today cannot. This inequality, together with the fact that middle- and low-income countries are more vulnerable to climate change, puts a great responsibility on the high-income countries. Not only do the high-income countries need to radically reduce their emissions, but they must also support middle- and low-income countries in reaching a growth and development pathway that has a lower carbon dioxide emission level compared to their own (Romani, Rydger and Stern, 2012). These different economic development pathways are the heart of what this paper aims to scrutinize; Have middle-income countries changed their economic growth approach to a lower emission pathway, compared to what high-income countries did?

According to the World Bank in the latest report on extreme poverty is that approximately 700 million people live in extreme poverty. Extreme poverty is when a person lives on less than 1.90\$ a day. Due to Covid-19, this number is expected to rise in 2020 (Overview,

2020). However, if the economic growth approach is not changed in the middle-income countries and continues in the same pattern as high-income countries have done, the effect on the CO<sub>2</sub> emissions may worsen the possibilities for future developing in less economic developed countries.

### **1.1 Background**

Human activity has an increasing impact on the earth's climate (IPCC, 2007) and ecosystems (Millennium Ecosystem Assessment, 2005). It is the human activity that indirectly or directly affects the composition of the atmosphere that the United Nations Framework Convention on Climate Change (1992) defines as climate change. The most critical human contributor to climate change is carbon dioxide in the atmosphere, and this is increasing rapidly (Canadell et al., 2007). Human activities have increased so much that it presently represents the dominant driving force of change to the earth system (Steffen, Crutzen, and McNeill, 2007).

Awareness and attention of climate change have risen significantly in recent years and is now considered one of the most critical challenges for development. It can be noted, among other things, that a global climate agreement from Paris came into force in 2016, where the core of the deal is to reduce greenhouse gas emissions and to support those affected by climate change (UNFCCC, 2015). Despite much polarization in the issue of the importance of climate change among politicians and the media, one sees a growing concern of it. For instance, environmental issues are one of the most important political questions in Sweden (Novus Group International AB, 2019). In the US, climate change has risen to become the most important issue for Democrats / Democratic-leaning independents who are registered to vote (Social Science Research Solutions, Inc, 2019). With the US exit from the Paris Agreement (Chakraborty, 2017), sound and valid policies that deal with climate change remain.

“One can say that we have enjoyed economic development and rich living standards while sacrificing the environment to global warming” (Katsuhisa Uchiyama, 2016). The relationship between economic growth and carbon dioxide is something that has been discussed over the last decades. Some with the belief that economic development is responsible for greenhouse gas and some with the belief that it cannot be fixed without a

developed economy. The pollution of carbon dioxide is positively correlated with urbanization, income level, and energy consumption (Shao et al., 2014). In a study done in Pakistan, the rapid pace of economic development, from agriculture to industrialization, increases the demand for energy heavily. As of today, environmentally friendly energy sources cannot compete with fossil fuel sources. Therefore, in developing countries, environmental degradation is key for further economic development (Khan, Khan, and Rehan, 2020).

According to the Environmental Kuznets Curve (EKC), there is a relationship between environmental devastation and economic growth. At the beginning of economic growth, the effects on the environment are small and slightly increasing when moving towards industrialization and middle-income countries. Until a turning point when the environmental devastation starts to decrease as the economy increases and to create the “inverted U shape” (Grossman and Kreuger, 1991). The EKC has been criticized by many (Stern, 2004). He suggests it is faster on the way to the turning point than after. In other words, the increase until the turning point is steeper than after, for the same level of economic development before the turning point, the increase is larger in CO<sub>2</sub> than the decrease after. It has also been tested if there is an N-shaped EKC. That meaning, after a certain level of income, the environmental devastation starts to rise again (Lorente, Álvarez-Herranz, 2016).

Climate change, global warming, and economic development are two topics that are discussed a lot around the world by leaders, activists, and media. However, we still lack research focusing on middle-income countries specific. MICs have the fastest growth on average and are home to most of the people in the world. Therefore, we chose to test these specifically to see if any conclusions can be made whether the turning point is significantly lower.

## **1.2 Purpose**

The purpose of this thesis is to investigate how economic development affects carbon dioxide emissions in countries classified as middle-income and high-income countries. The goal is to see if there is a difference between middle-income- and high-income countries' development by using the theory of the Revised Environmental Kuznets Curve.

## 2. Theoretical framework

---

*The purpose of this section is to provide a review the theoretical background of the relationship between income and pollution.*

---

### 2.1 Kuznets Curve (KC)

The notion of the Kuznets curve (KC) is extracted from the work of Simon Kuznets in 1955, where he began to confront economic equality's relationship with economic development. He noted that development in developing countries usually is associated with a transition from agriculture society with most of the people living in the countryside to industrialization where most people are moving into the cities. At the beginning of this economic development harms economic equality, but after a certain point, this will change to economic development, having a positive effect on economic equality. Hence there is a nonlinear relationship between economic development and economic equality (Kuznet, 1955).

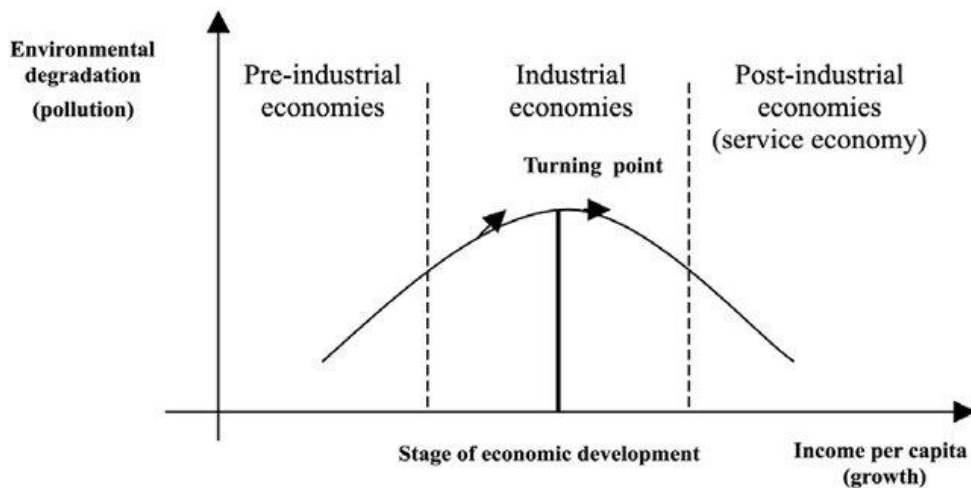

Although the idea behind Kuznet's original paper was more speculative than empirical, his theory has been of great significance, and the relationship that Kuznet found between economic development and economic equality was later called the Kuznets U-hypothesis (Kapuria-Foreman & Perlman, 1995).

#### 2.1.1 Environmental Kuznets Curve (EKC)

When analyzing the relationship of per capita income to air pollution per capita, a nonlinear relationship similar to Kuznet's U-hypothesis has been noted. This relationship shows that a country's early economic development degrades the environment until what is called the turning point is reached, after which the environment improves with further economic development. This relationship is referred to as the environmental Kuznets curve (Grossman & Krueger, 1995).

Figure 1 Environmental Kuznets Curve

**Source:** Panayotou (1993)

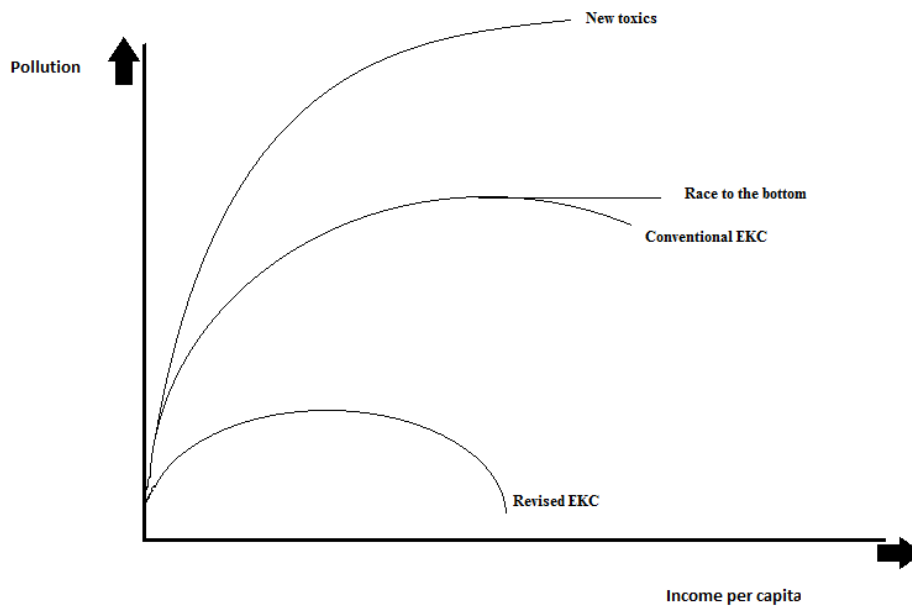

There is little evidence to validate the inverted U ratio that EKC predicts (Stern, 2004), and a typical and predictable relationship between per capita income and pollution is questionable (Copeland & Taylor, 2003).

In cases where a relationship comparable to what EKC predicts is noticed, there may be underlying reasons for why the relationship arises, and this means that one cannot apply EKC as a general theory to the development of all countries. The underlying reasons of why an inverted U-relationship is noticed may be due to trade between countries and the fact that developed countries generally have more environmental regulations compared to developing countries. According to the Heckscher-Ohlin trade theory, countries will specialize in their production to goods whose factors they are relatively abundant in and then trade the excess of those goods with other countries. Developed countries are predicted to produce goods that require relatively more labor and capital, while developing countries are predicted to produce goods that require more labor. Since different types of productions have different effects on the environment, this specialization may be one of the reasons why the inverted U-ratio is noticed (Stern, 2004).

### 2.1.2 Revised Environmental Kuznets Curve

Dasgupta et al. (2002) presented an alternative view of the EKC, where he explains four different views on the relationship between pollution and income, which are seen in Figure 2.

Figure 2 Environmental Kuznets Curve: Different Scenarios

Source: Dasgupta et al. (2002) and Perman and Stern (2003)

The different scenarios exist because the burden of proof for the original EKC is flawed. Two pessimistic views are referred to as race to the bottom and New toxic. The idea of the race to the bottom is that some critics of the EKC claim that globalization causes the emission levels to rise and stay at the absolute maximum level in a so-called "race to the bottom" of the environmental standard. Other pessimistic critics argue that the original EKC relationship may be right for some emissions. However, with economic development, new emissions will be created, which will mean that absolute emissions always rise with economic development, which is referred to as New Toxic. A more optimistic view is that of the Revised EKC, where it is assumed that the developed countries' innovations have a positive spillover effect in today's developing countries. This spillover effect and the liberalization that has taken place in developing countries in recent decades means more efficient handling of inputs and that environmentally hazardous activities are subsidized to a lesser degree. This spillover effects and liberalization leads that today's developing countries will have a lower peak level of environmental degradation than today's developed countries had (Dasgupta et al., 2002).

Stern (2004) considered that the relationship between emissions and per capita income is probably a mixture of two different scenarios that Dasgupta et al. (2002) called New Toxics and Revised EKC.

## **2.2 Previous empirical studies**

After Grossman & Kreuger introduced the EKC in 1995, a lot of studies have been done on the EKC. One of the most known is the critique in Stern (2004). Stern's critiques were that the EKC was weak in terms of econometrics. Stern argues that there wasn't taking enough of consideration of possible problems with either stochastic trends or time series. The conclusion from Stern is that the evidence of the EKC is that it is statistically weak for the inverted U-shape (Stern, 2004).

Furthermore, in 2004 the EKC was reviewed by Dinda. This study by Dinda was looking at different previous studies on the EKC and the inverted U-shape. With the goal of proving if the theory of EKC holds or not. The findings of Dinda are that in countries' early stages of economic development, the focus on the climate is lower than in later stages of their economic development. That proves the main standpoint of the EKC. However, the result also shows that the turning point is not consistent; it varies a lot across studies for the same indicators. Another founding is that when countries become more economically developed, the productions tend to be outsourced to less developed countries with less interest in the climate. (Dinda, 2004)

Another study by Shahbaz and Sinha (2019), surveyed previous empirical papers were done on EKC and CO<sub>2</sub>. One of the main reasons for their paper is when MICs are developing into developed countries, their need for electricity is increasing, and with increased energy consumption, the CO<sub>2</sub> emissions generally increase. The main findings of Shahbaz and Sinha conclude that there is a lack of studies that include the height of the EKCs. One question to be answered is if there is any turning-point beyond certain levels of CO<sub>2</sub> emissions.

### 2.3 Hypothesis

The hypothesis to be tested is:

- 1) Middle-income and high-income countries' economic development between 1960 and 2014 is correlated with the CO<sub>2</sub> emissions rate according to the Environmental Kuznets curves predictions.
- 2) Middle-income countries have an, on average, lower and earlier turning point than high-income countries.

These hypotheses reflect the environmental Kuznets Curve, which is an economic theory that will be examined in this paper. The first hypothesis will test if the variables are correlated and if so, does the relationship follow the curve predicted by economic theory. The selection of focusing the paper on CO<sub>2</sub> emissions is both because it is the greenhouse emission that contains the foremost data and the fact that CO<sub>2</sub> emissions are one of the foremost vital contributors to global climate change (Houghton et al. 2001).

The second hypothesis tests if middle-income countries have transitioned to low carbon growth and development paths earlier compared to developed countries.

### 3. Empirical Framework

---

*In this section, we will present the data set and the variables used in the empirical tests in section 4 as well as the models. This section will also provide descriptive statistics.*

---

#### 3.1 Methodology

The environmental Kuznets curve theory predicts that emissions per capita initially have a positive correlation with GDP per capita. However, after a certain level of GDP per capita, the relationship becomes negative. Hence the theory predicts an inverted U-shape. The Environmental Kuznets curve postulates a nonlinear relationship between income and pollution. To test the first hypothesis, we follow the empirical studies on the EKC using the following model:

$$Y_{it} = \alpha_i + \beta_0 X_{it} + \beta_1 X_{it}^2 + \varepsilon_{it} \quad (\text{Dinda, 2004}). \quad (1)$$

Where  $Y_{it}$  is pollution per capita,  $X_{it}$  is the income per capita, and  $X_{it}^2$  is the income per capita squared.  $\alpha_i$  is the intercept,  $\beta_0$  and  $\beta_1$  are the coefficients of the independent variables. The  $\varepsilon_{it}$  is the error term that captures the variation in  $Y_{it}$  that is not explained by  $X_{it}$  or  $X_{it}^2$ . While  $i$  is 1,2,3... $n$  countries and  $t$  is 1,2,3... $t$  years. If  $\beta_0 > 0$  and  $\beta_1 < 0$ , the EKC relationship between pollution per capita and income per capita would exist.

The second hypothesis: MIC: s has an, on average, lower turning point than high-income countries. We will use the coefficient retrieved from the regression one in order to calculate the predicted maximum of emissions, i.e., the turning point for the different panels. The turning point is calculated as:

$$T = \left( -\frac{\beta_1}{2\beta_2} \right) \quad (\text{Dinda, 2004}) \quad (2)$$

According to our hypothesis, the turning point calculated by equation 2 will be significantly lower for MIC's compared to HIC's.

The data used in the empirical research are annual data estimated for the years available for each country with a max period of 1960-2014, hence a maximum of 54 observations per variable for each country. The variables used are GDP per capita (constant 2010 US\$) and CO<sub>2</sub> emissions per capita, and both are collected from the World Bank. GDP per capita takes the value of the gross domestic product divided by midyear population at

constant 2010 U.S. dollars value. CO<sub>2</sub> emissions per capita are measured in tons of carbon per capita, which is calculated from fossil fuel consumption and cement production. Fuels delivered to ships and aircraft in international transport are excluded from the calculations due to difficulties in distributing the fuels among the different countries.

The first step is to divide the countries into panel data. We will make panel data for high-income countries and middle-income countries for an aggregate comparison between the different classifications of countries. We need to be sure we can perform a regression of the variables without it being a spurious regression. To check that the regressions are not spurious, we will need to conduct some tests. First, will we conduct a panel cointegration test to decide whether the time series variables in the panel are stationary or not. Further, a test to check if the variables are correlated or not will be performed. It will be tested with panel cointegration tests, which is a test that analyses the long-run relationship between the variables. If the variables are non-stationary at level and become stationary after equal amounts of difference and then share a long-run relationship, the regression will not be spurious.

### **3.2 Descriptive Statistics**

The World Bank classifies countries based on their income levels. Currently, there are four different classifications: Low-income countries, Lower-middle-income countries, Upper-middle-income countries, and High-income countries. The income levels are measured by gross national income (GNI) per capita, in U.S. dollars, converted from the local currency, and the country classification is updated once a year.<sup>1</sup> We have used the World Bank's latest classification for our data, and we have merged Lower-middle-income countries and Upper-middle-income countries into what we call middle-income countries. A full list of which countries belong to the different classifications can be seen in Appendix 1.

In Table 1, the descriptive statistics for HIC and MIC can be found. The values of the variables GDP per capita and CO<sub>2</sub> per capita differ dramatically between HIC and MIC countries. Interestingly HIC has a lower minimum GDP per capita compared to MIC,

---

<sup>1</sup> How does the World Bank classify countries? - World Bank Data Help Desk, 2020

which is due to the World Bank classifies countries based on gross national income per capita, which may differ GDP per capita very much. The maximum and mean values for both variables are higher in the HIC countries. Still, the high standard deviation in all variables means that it differs a lot even between countries in the same classification.

Table 1 Descriptive Statistics aggregate HIC and MIC

<b>Classification</b>	<b>Variable</b>	<b>N</b>	<b>Minimum</b>	<b>Maximum</b>	<b>Mean</b>	<b>Std. Deviation</b>
<b>HIC</b>	GDP per capita	2639	0.677	141200.380	26875.845	19454.061
	CO <sub>2</sub> per capita	2639	0.0411	67.3105	9.619	8.009
<b>MIC</b>	GDP per capita	4238	132.303	20512.940	3240.369	2751.451
	CO <sub>2</sub> per capita	4235	0.004	15.940	1.939	2.284

## 4. Results

---

*This section will provide the result from the empirical tests, which have been conducted in line with the empirical framework provide in section 3.*

---

All tests presented in the paper are done in E-views, and full details of all the tests can be found in the Appendices.

### 4.1 Test to determine the econometric model

Before we can investigate the relationship between the independent variables and the dependent variable in Equation 1, we must first examine whether the variables are stationary or not. If all the variables are non-stationary, then we cannot be sure of the result from the OLS-regression is correct because of the risk that it is a spurious regression. A spurious regression is when one regresses a non-stationary variable on another non-stationary variable(s). Even if a long-term relationship doesn't exist between the variables, a spurious regression has the consequence that the relationship between the variables can be significant anyhow due to either coincidence or some other factor not included in the regression (Granger and Newbold, 1974). To avoid a false regression, we examine the variables through a panel root test.

Table 2 Result of panel unit root test

Classification	Variable	LLC		IPS	
		Level	First difference	Level	First difference
<b>MIC</b>	CO <sub>2</sub> per capita	5.382	-67.233	2.638	-65.105
		(1.000)	(0.000)	(0.996)	(0.000)
	GDP per capita	37.217	-29.464	27.949	-35.372
		(1.000)	(0.000)	(1.000)	(0.000)
	(GDP per capita) ^2	65.247	-17.204	44.763	-29.761
		(1.000)	(0.000)	(1.000)	(0.000)
<b>HIC</b>	CO <sub>2</sub> per capita	5.395	-55.599	3.392	-52.306
		(1.000)	(0.000)	(1.000)	(0.000)
	GDP per capita	1.228	-27.887	9.222	-27.119
		(0.890)	(0.000)	(1.000)	(0.000)
	(GDP per capita) ^2	13.913	-25.962	18.057	-25.882
		(1.000)	(0.000)	(1.000)	(0.000)

Note: The lag selection for every variable is based on Akaike Info Criterion. LLC and IPS tests for all the series include a constant as an intercept.

A panel unit root test is not the same as a unit root test for a time series data. There are two different types of panel unit root tests, common unit root process, and individual unit root process. Levin, Lin, and Chu (2002) use the common unit root process, which holds that the persistence parameters are standard across cross-sections. Im, Pesaran, and Shin (2003) use the individual unit root process, which instead assumes that the persistent parameters move freely across cross-sections. To be sure of the stationarity of the variables, we use both the test formulated by Levin, Lin, and Chu (LLC) and the one formulated by Im, Pesaran, and Shin (IPS). The results representing these tests can be found in Table 3, where they are presented for MIC and HIC. Table 3 shows that at a significance level of one percent that both tests show that all variables for both MIC and HIC are non-stationary and that it becomes stationary after the first difference.

Since the panel unit root test showed that the variables are non-stationary and that they become stationary after the first difference, we performed a panel integration test to investigate the long-term relationship between the variables. We have chosen to use two different panel integration tests, one test introduced by Pedroni (1999) and another test developed by Maddala and Wu (1999), which is referred to as the Johansen Fisher panel integration test.

Pedroni (1999) derives seven different panel test statistics. Of these seven statistics, four are based on within-dimension, and three are based on between-dimension. Both the within-dimension statistics and between-dimension statistics have a null hypothesis of no cointegration for the panel and an alternative hypothesis of cointegration for the panel. In table 3, the Pedroni residual cointegration test is presented for MIC and HIC. Both for MIC and HIC, the null hypothesis is rejected in 6 out of 7 tests. Hence, we assume that there is cointegration of the variables in the panel.

Table 3 Results Pedroni residual cointegration test for equation 1

Classification	Tests	Statistics	Probability
<b>MIC</b>	Panel v-Statistic	-2.494	0.994
	Panel rho-Statistic	-2.207	0.014
	Panel PP-Statistic	-6.861	0.000
	Panel ADF-Statistic	-3.969	0.000
	Group rho-Statistic	-2.661	0.005

	Group PP-Statistic	-2.663	0.004
	Group ADF-Statistic	-2.409	0.008

Table 4 Results Johansen Fisher panel cointegration test for equation 1

Classification	No. of CE(s)	Hypothesized Fisher Stat		Fisher Stat	
		(from trace test)	Prob.	(from max-eigen test)	Prob.
<b>MIC</b>	None	1045.446	0.000	880.511	0.000
	At most 1	406.616	0.000	358.023	0.000
	At most 2	304.313	0.000	304.313	0.000
<b>HIC</b>	None	517.871	0.000	436.748	0.000
	At most 1	207.082	0.000	171.732	0.001
	At most 2	189.065	0.000	189.065	0.000

The Johansen Fisher test developed by Maddala and Wu (1999) is testing both for the number of cointegration vectors and individual cointegration for the different cross-sections. The results of the Johansen Fisher panel cointegration test can be found in Table 4. To not make the table too big, we have chosen only to include the tests of the number of cointegration vectors in Table 4, and the test of individual cointegration for the different cross-sections can be found in the appendix. The tests of the number of cointegration vectors have a null hypothesis of at most  $r$  cointegration vectors. The null hypothesis is rejected on the level of at most two cointegration vectors for both MIC and HIC, which states that

there are more than two cointegrated vectors in our variables. Hence, a long-run relationship exists between more than two of our variables, which makes it possible for us to regress all our variables without the regression being spurious.

Since it was found that the variables are cointegrated, the next step before we can estimate long-run coefficients for the independent variables is to determine if we should use the random effect model (REM), Fixed effect model (FEM) or Pooled OLS model for our panel data regression. With the Pooled OLS model, one neglects the cross-section and time-series nature of the data and estimates an aggregate regression by pooling all observations. In the fixed-effect model, one also pools the observation but either allows for each cross-section unit to have its own intercept through the use of dummy variables or express each unit's variable as a deviation from its mean value. The random effect model assumes that each unit has its own intercept value that is a random drawing from a population of units.

To test which estimation technique to use, we will first use the Lagrange Multiplier Tests for Random Effects, which is a group of tests that all originated from Breusch-Pagan (1980). The null hypothesis of the test is that the variance of the random effect is zero, and one should use Pooled OLS against the alternative hypothesis that the variance of the random effect is larger than zero and should use REM. Secondly, we investigate if REM appropriate by using a test by Hausman (1978). The null hypothesis of the Hausman test is that REM is suitable against the alternative hypothesis that REM is not suitable.

Table 5 Lagrange Multiplier Tests for Random Effects

<b>Lagrange Multiplier Tests for Random Effects</b>				
<b>Classification</b>	Test	Cross-Section	Time	Both
<b>MIC</b>	Breush-Pagan	37195.666	3.952	37199.619
		(0.000)	(0.047)	(0.000)
<b>HIC</b>	Breush-Pagan	1.9338.859	2.339	19341.20
		(0.000)	(0.126)	(0.000)

Table 6 Correlated Random Effects - Hausman Test

Correlated Random Effects - Hausman Test				
Classification	Test Summary	Chi-Sq. Statistic	Chi-Sq. d.f.	Prob.
<b>MIC</b>	Cross-section random	7.451	2	(0.024)
<b>HIC</b>	Cross-section random	11.555	2	(0.003)

The result from the tests can be found in Tables 6 and 7. For both MIC and HIC, the result of the Lagrange multiplier test states that at a one percent significance level, REM is preferred to pooled OLS for cross-section while pooled OLS is preferred to REM for time. Hence, we need to test cross-section in the Hausman test to decide if one should use REM or FEM. For both MIC and HIC, the significance level is quite low, and the null hypothesis is rejected at 5% and 1% significance level, respectively. Hence, we chose to regress both MIC and HIC with cross-sectional fixed effects.

#### 4.2 First hypothesis

Middle-income and high-income countries' economic development between 1960 and 2014 is correlated with the CO<sub>2</sub> emissions rate according to the Environmental Kuznets curves predictions.

The results from the regression of equation one using FEM can be found in table 7. According to the results, the coefficient on GDP per capita is positive and statistically significant, and the coefficient on squared GDP per capita (GDP2) is negatively significant, which is in line with our first hypothesis. As seen in Table 7, at a low level of GDP per capita, an increase in GDP per capita increases the CO<sub>2</sub> emission per capita, but after a certain point, a further increase in GDP per capita decreases CO<sub>2</sub> emission per capita, which is the relationship that the EKC predicts.

Table 7 Results of regression for equation 1 using Least Squares FEM

Classification	Variable	Coefficient	Std. Error	t-Statistic	Prob.
<b>MIC</b>	GDP2	-1.35E-08	1.27E-09	-10.600	0.000
	GDP_PER_CAPITA	6.03E-04	1.88E-05	32.100	0.000
	C	2.29E-01	4.22E-02	5.430	0.000
<b>HIC</b>	GDP2	-1.45E-09	1.77E-10	-8.180	0.000
	GDP_PER_CAPITA	1.93E-04	1.76E-05	11.000	0.000
	C	6.01E+00	3.15E-01	19.100	0.000

Serial correlation is common in multi-country GDP series due to dependence arising from global shocks and other more complicated interdependencies (Phillips and Moon, 1999). Because of the risk of serial correlation, we will also regress the equation using a fully modified least square (FMOLS) estimation method developed by Phillips and Moon (1999), which is estimated with a non-parametric approach that includes the alterations to tackle the serial correlation. By including a second approach for the regression, we are adding extra support to reject or accept the null hypothesis.

The results of equation 1 using FMOLS can be found in table 8, and we see that the results using FMOLS are very similar to using Least Squares with a fixed-effect model for cross-section seen in table 7. The coefficients for the variables using FMOLS are between -3% and + 3% compared to coefficients for the variables using the Least Squares with a fixed-effect model for cross-section.

Table 8 Results of regression for equation 1 using FMOLS

Classification	Variable	Coefficient	Std. Error	t-Statistic	Prob.
<b>MIC</b>	GDP2	-1.39E-08	2.28E-09	-6.100	0.000
	GDP_PER_CAPITA	6.09E-04	3.38E-05	18.000	0.000
<b>HIC</b>	GDP2	-1.48E-09	3.09E-10	-4.00	0.000
	GDP_PER_CAPITA	1.89E-04	3.09E-05	6.110	0.000

### 4.3 Second hypothesis

Middle-income countries have an, on average, lower and earlier turning point than high-income countries.

Before we can calculate the turning point for MIC and HIC, we want to know that the predicted regression lines are significantly different from each other. To do this, we have regressed all countries aggregated using equation 1 with cross-sectional fixed effects and dummy variable (D1) for MIC. The result from the regression can be found in Table 9, and in the table, we see that each variable is statistically significant, which means that the regression lines are significantly different for MIC and HIC.

Table 9 Results of regression for equation 1 using Least Squares FEM with dummy

Variable	Coefficient	Std. Error	t-Statistic	Prob.
<b>GDP_PER_CAPITA</b>	1.93E-04	1.12E-05	17.324	0.000
<b>GDP2</b>	-1.45E-09	1.12E-10	-12.897	0.000
<b>GDP_PER_CAPITA*D1</b>	4.10E-04	6.99E-05	5.858	0.000
<b>GDP2*D1</b>	-1.21E-08	4.68E-09	-2.579	0.000
<b>C</b>	2.449	0.123	19.991	0.000

To calculate the turning point for MIC and HIC, we use equation 2 with the coefficient from Table 7 and Table 8.

*Turning point of the EKC for MIC using result from table 7*

$$= \frac{6.03E - 04}{2 * -1.35E - 08} = \$22\ 301$$

*Turning point of the EKC for HIC using result from table 7*

$$= \frac{1.93E - 04}{2 * -1.45E - 09} = \$66\ 786$$

*Turning point of the EKC for MIC using result from table 8*

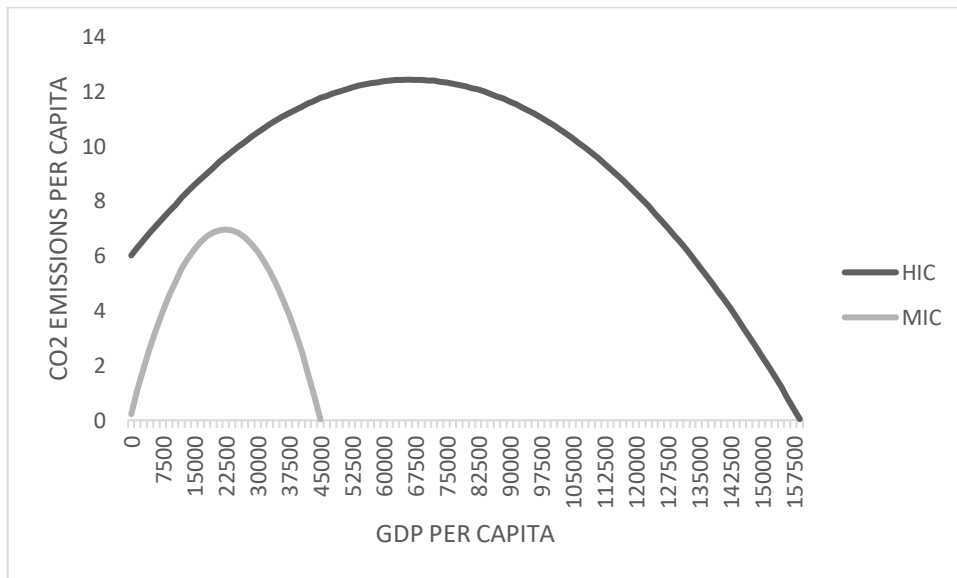

$$= \frac{6.09E - 04}{2 * -1.39E - 08} = \$21\ 916$$

*Turning point of the EKC for HIC using result from table 8*

$$= \frac{1.89E - 04}{2 * -1.48E - 09} = \$63\ 632$$

The calculations state that MIC CO<sub>2</sub> emissions will decrease once GDP per capita reaches \$21916 - \$22301, which is much earlier compared to HIC that has a turning point at GDP per capita of \$63632 - \$66786. By calculating the CO<sub>2</sub> emission at the respective turning point using the regression of the Least Squares Fixed effects model in Table 7 we also find the maximum level of CO<sub>2</sub> emissions. For MIC, the CO<sub>2</sub> emission reaches 6.96 metric tons of carbon per capita, and for HIC, it reaches 12.43 metric tons of carbon per capita. A visualization of the relationship between CO<sub>2</sub> emission per capita and GDP per capita based on the results in Table 7 is shown in Figure 3. In the graph one clearly sees that the different relationship for MIC and HIC is in line with our second hypothesis.

Figure 3 Predicted development

## 5. Analysis

---

*This section will analysis the results in section 4, in line with the theoretical framework in section 2.*

---

The first empirical test of this paper was the correlation between economic development and CO<sub>2</sub> emission from 1960 to 2014. The test was divided between all 107 middle- and all 77 high-income countries, according to the World Bank. The middle-income are all merged from the World Banks' lower- and upper-middle-income countries. The GDP per capita was used as the explanatory variable and CO<sub>2</sub> emissions per capita the response; this in line with the EKC from Grossman and Kreuger (1995). The theory of EKC predicts that in the early stages of an economy's development, CO<sub>2</sub> emissions will increase until a certain level of what is called the turning point, after which further economic development has a negative effect on the CO<sub>2</sub> emission. This will be formed as an inverted U-shape. The result was as expected, and it confirms the EKC inverted U-shape for both MIC's and HIC's.

The second empirical test of our paper tests whether the relationship is similar to what the Revised EKC by Dasgupta et al. (2002) assume. The theory assumes that middle-income countries, on average, have a lower and earlier turning point than high-income countries. The Revised EKC suggests that countries that are later in their economic development have a lower turning point of the inverted U-shape than already developed countries. The result of the test showed a significantly lower turning point average for MIC's compared to HIC's both at a 1 percent level of significance. If all these countries have reached the turning-point is something that is not tested for. Hence the numbers are just an average based on a panel-test.

In section 2.1.2, the Revised EKC is discussed and the two pessimistic views, race to the bottom and new toxic. Dasgupta questions if CO<sub>2</sub> emission is replaced by other emissions when GDP per capita increases. However, this is difficult to study since, in many countries, other types of emissions are not recorded as the CO<sub>2</sub> emissions. Hence data on them is lacking. That lacking data of other emissions is the reason why this paper only tests for CO<sub>2</sub>.

The EKC is a highly debatable theory were some scholars criticize the whole existence of it and while others argue that it follows another path, where the race to the bottom scenario is one of the most known. This scenario argued by Dinda (2004), is that while HIC controls their emissions with cost heavily regulations, the incentive for firms in HIC's is to outsource their production to less-developed countries. In the less-developed countries, the priority is on jobs and economic development rather than clean air and pollution.

Outsourced production increases trade, and several studies have been studying trade openness and its relationship to CO<sub>2</sub> emissions. Atci (2009) researched this relationship in four countries throughout 22 years. The result was that trade openness had a negative impact on CO<sub>2</sub> emissions. That could be one factor why further developed countries can lower their CO<sub>2</sub> emissions while it is increasing in less developed. The less developed countries transformation from agricultural to industry. According to Shao et al. (2014), there is a positive correlation between industrialization, urbanization, and energy consumption. The environmentally friendly energy cannot compete in terms of price with fossil fuel energy. Therefore, expensive low carbon energy will not be used by less developed countries.

As mentioned earlier, this study was conducted on a total of 184 countries, divided into only two panels, and only three variables GDP per capita, GDP per capita squared, and CO<sub>2</sub> per capita. While our study shows confirmation of the EKC and the Revised EKC, the result needs to be taken with caution due that the study was only dividing the countries into two different economic stages while using only two independent variables. It could be other differences that explain the economic development and CO<sub>2</sub> emissions, such as region, sociological factors, size of the country, natural resources, other emissions, export, and import. The main overall reason why only these variables are used is due to a lack of data. The only emission World Bank has for all these countries from the 1960s is CO<sub>2</sub> emissions. Furthermore, the impact of import and export is something that is hard to count. Do the emissions from the production count in the imported goods, or does it count as the production country's emissions? Nonetheless, we did try to divide the countries into different regions based on the World Banks' different classifications. Somehow, we did not manage to test this econometrically, mostly due to a problem with spurious

regressions. Due to these complex situations, we decided to use the data provided by the World Bank and fewer variables.

## 6. Conclusion

Two different questions have been tested in this paper. The first question tested the Environmental Kuznets Curve's existence in the middle- and high-income countries. The middle-income countries are the World Bank's two groups of low- and upper-middle economies. The high-income countries are the economies that World Bank classifies as high-income or OECD. The test was conducted throughout the years between 1960-2014 and the three variables  $CO_2$ , GDP, and  $GDP^2$ , was used. The result confirmed the existence of the EKC and the inverted-U shape for both middle- and high-income countries, all at a 1 percent level of significance.

The second empirical question of this study was if the turning point on the Revised Environmental Kuznets Curve is significantly lower for middle-income countries compared to high-income countries. The data was the same as for the first test. The result confirmed that the turning point for middle-income countries was significantly lower, all at a one percent level of significance. We did test this panel data with both FMOLS and Fixed effect models. The result was similar for both tests. The average turning point for middle-income countries was approximately \$22 000 per capita, while for high-income countries, approximately \$64 000 per capita. 2010 is used as the constant for GDP per capita.

This leaves room for many further studies. Once the turning point has been reached, do other emissions increase while  $CO_2$  decreases? Could there be other factors than GDP per capita that affects  $CO_2$  emissions? For example, countries' energy sources, sociological factors, or natural resources. These are all interesting variables that we could see have an impact on the  $CO_2$  emissions and Environmental Kuznets Curve.

\* Probabilities are computed using asymptotic Chi-square distribution.

## Johansen Fisher panel cointegration test HIC

Johansen Fisher Panel Cointegration Test  
 Series: CO2\_PER\_CAPITA GDP\_PER\_CAPITA GDP2  
 Date: 03/17/20 Time: 13:17  
 Sample: 1960 2014  
 Included observations: 4235  
 Trend assumption: Linear deterministic trend  
 Lags interval (in first differences): 1 1

### Unrestricted Cointegration Rank Test (Trace and Maximum Eigenvalue)

Hypothesized No. of CE(s)	Fisher Stat.* (from trace test)	Prob.	Fisher Stat.*	
			(from max-eigen t...	Prob.
None	517.9	0.0000	436.7	0.0000
At most 1	207.1	0.0000	171.7	0.0014
At most 2	189.1	0.0001	189.1	0.0001

\* Probabilities are computed using asymptotic Chi-square distribution.

F-statistic	142.7309	Durbin-Watson stat	0.219049
Prob(F-statistic)	0.000000		

## Regression result MIC using FMOLS

Dependent Variable: CO2\_PER\_CAPITA  
 Method: Panel Fully Modified Least Squares (FMOLS)  
 Date: 04/11/20 Time: 09:02  
 Sample (adjusted): 1961 2014  
 Periods included: 54  
 Cross-sections included: 104  
 Total panel (unbalanced) observations: 4157  
 Panel method: Pooled estimation  
 Cointegrating equation deterministics: C  
 Coefficient covariance computed using default method  
 Long-run covariance estimates (Bartlett kernel, Newey-West fixed bandwidth)

Variable	Coefficient	Std. Error	t-Statistic	Prob.
GDP2	-1.39E-08	2.28E-09	-6.103328	0.0000
GDP_PER_CAPITA	0.000609	3.38E-05	18.03006	0.0000
R-squared	0.921298	Mean dependent var		1.953794
Adjusted R-squared	0.919258	S.D. dependent var		2.289052
S.E. of regression	0.650437	Sum squared resid		1713.849
Long-run variance	1.293825			

## Regression result HIC using FMOLS

Dependent Variable: CO2\_PER\_CAPITA  
 Method: Panel Fully Modified Least Squares (FMOLS)  
 Date: 04/11/20 Time: 09:06  
 Sample (adjusted): 1961 2014  
 Periods included: 54  
 Cross-sections included: 61  
 Total panel (unbalanced) observations: 2580  
 Panel method: Pooled estimation  
 Cointegrating equation deterministics: C  
 Coefficient covariance computed using default method  
 Long-run covariance estimates (Bartlett kernel, Newey-West fixed bandwidth)

Variable	Coefficient	Std. Error	t-Statistic	Prob.
GDP2	-1.48E-09	3.09E-10	-4.799506	0.0000
GDP_PER_CAPITA	0.000189	3.09E-05	6.107135	0.0000
R-squared	0.786848	Mean dependent var		9.633882
