Abstract

Novel multifunctional NiFe$_2$O$_4$/MWCNTs/ZnO hybrid nanocomposite has been successfully synthesized via the hydrothermal and the co-precipitation methods at 210 °C and 90 °C, respectively, to be used as a solar radiation driven photocatalytic material. The hybrid nanocomposite exhibits enhanced photocatalytic activity compared to NiFe$_2$O$_4$ and ZnO for decolorization of Methylene Blue (MB) dye - as a model pollutant- from aqueous solutions under solar radiation. Different complementary analytical tools were used to investigate the structural, optical and magnetic properties of the photocatalyst which possess good light response ability, photocatalytic stability, magnetic separation performance and reproducibility. The results from optical degradation confirmed the synergistic effect between the NiFe$_2$O$_4$, the ZnO and the MWCNTs. Suppressed recombination of electron–hole pairs mean more efficient charge separation and enhanced photocatalytic activity. The apparent rate constant ($k_{app}$) of the MB decolorization for a duration of 300 minutes using NiFe$_2$O$_4$/MWCNTs/ZnO, NiFe$_2$O$_4$ and ZnO photocatalysts were found to be 0.00438 min$^{-1}$, 4.12857E$^{-4}$ min$^{-1}$ and 0.002 min$^{-1}$, respectively. The removal efficiency was also investigated for different pH values. Due to the magnetic properties of the nanocomposite, it was possible to separate it after degradation experiments and hence re-usability is possible. In view of the enhanced solar radiation driven photodegradation, the present composite can present a robust alternative as a solar radiation driven photocatalyst.

Key words: Magnetic carbon nanotubes (Mag-CNTs); NiFe$_2$O$_4$ nanoparticles; Photocatalytic degradation, Magnetic separation.

1. Introduction

The process industry is developing at an extremely rapid pace however one of the great challenges faced are the environmental pollution effects [1-7]. Most synthetic dyes employed in textile, cosmetics and other products have high contents of colored components, salts, organic contaminants and high chemical oxygen demand. They cannot be eliminated efficiently by conventional chemical oxidation and traditional biodegradation methods due to their stable complicated aromatic molecules [8]. Carbon nanotubes (CNTs) have been proven to acquire a great potential as a superior adsorbent for eliminating many kinds of inorganic and organic pollutants from aqueous solutions, due to their small pore size, large specific surface area, hollow and layered structures [9]. Functionalization of the CNTs surface with different materials like polymers, metals, metal oxides and complex metal oxides can develop CNTs features and will possess potential applications as magnetic data storage [10], electric devices [11] and heterogeneous catalysis [12].

It is believed that a remarkable improvement of the photocatalytic activity can be achieved via the combination of CNTs and a suitable semiconductor due to the synergistic effect [13-16]. The semiconductors alone display some photocatalytic effect, but the limitations diminish their wider applicability. The anchoring of semiconductors with multi-walled carbon nanotubes (MWCNTs), overcome such limitations and make semiconductor composites better photocatalyst materials [17].

Among the many semiconductors used in the field of photocatalysis are TiO$_2$, ZnO and CdS [18-23]. ZnO is widely used in photocatalytic degradation of organic pollutants [7]. It is well known as an excellent photocatalyst due to its superior features such as non-toxicity, lower cost synthesis possibilities and chemical stability [24, 25]. Most semiconductors basically absorb ultraviolet light [26, 27] which accounts for only 3%–5% of sunlight [19]. ZnO has a wide band gap (~3.37 eV) [7, 28], which is unfavorable for the absorption of solar visible light. However, ZnO possesses point defects that fills the band gap and enable the emission and absorption of the light energy in the visible range. To further improve the ZnO performance, several attempts have been made to increase the shift of its absorption band from UV to the visible light region by different approaches such as e.g. doping or coupling ZnO with metals, nonmetals, and metal oxides. The difficulty in isolating the ZnO and CNTs-based photocatalysts from aqueous solutions after usage limits their application in treatment of water polluted with dyes [24]. Although centrifugation, precipitation, filtration and other methods have been used to separate the photocatalysts from the reaction solution, the separation process is generally complex and time-consuming. Therefore, to solve the problem, and in order to separate the
photocatalysts conveniently after the reaction, magnetic carriers are introduced into the photocatalyst to prepare a good recyclable magnetic photocatalyst, for example, coupling of ZnO or CNTs with strong magnetic materials as spinal ferrites [29]. This is an alternative option for isolation by filtration or centrifugation [13, 30]. Furthermore, decoration of CNTs by spinel ferrites nanoparticles (NPs) which are very important magnetic materials, can improve the optical, electrochemical and magnetic properties of the CNTs [31]. In some investigations, MWCNTs decorated with NiFe2O4 NPs (NiFe2O4/MWCNTs) have proven to be an appropriate mediator in electrochemical processes [32]. Previous studies have clearly demonstrated that the synergistic effect through the decoration of CNTs by NiFe2O4 can improve the optical, electrochemical and magnetic properties of the CNTs [13, 33]. It is clearly demonstrated that it is possible to further promote the activity of the photoinduced charge separation leading to high photocatalytic efficiency due to the synergistic effect through the combination of ZnO [34-36] or NiFe2O4 [13, 33, 37] with CNTs to make hybrids for effective elimination of dye contaminants from aqueous solutions.

Likewise, coupling among ZnO and NiFe2O4 creates a semiconductor photocatalyst which enhances the photocatalytic activity under visible light [24, 38]. Theoretically, when ferrite composites are coupled with ZnO, a heterojunction is created and then the photoinduced electrons and holes are separated effectively, give rise to enhancement in the photocatalytic efficiency [39]. Zhu et al. [38] used NiFe2O4/ZnO hybrid prepared by the hydrothermal method for Congo red (CR) dye removal by adsorption and photocatalysis, then the magnetic hybrid was easily and effectively separated from the aqueous solution by an external magnet. Jamarun et al. [24] used the solvothermal method to prepare the same composite for photocatalytic Rhodamine B dye degradation under solar light. The two previous studies i.e. [24] and [38] reported that the photocatalytic activity of the synthesized nanocomposites were higher than pristine ZnO and pristine NiFe2O4. Zhu et al. [13] used NiFe2O4/MWCNTs hybrid prepared by the hydrothermal method to investigate its photocatalytic activity for the removal of Congo red (CR) dye from aqueous solutions under simulated solar light irradiation. It was found that the activity was 2.18 times higher than that of NiFe2O4. Seffah et al. [40] synthesized the same nanocomposite by hydrolysis using refluxing for 45 minutes which have been used for the elimination of methyl orange dye from polluted water.

In this study, novel multifunctional NiFe2O4/MWCNTs/ZnO photocatalyst has been synthesized via the hydrothermal and co-precipitation methods (two-steps process) and was investigated as an efficient visible light driven photocatalyst. The as-prepared composites were characterized using, UV-
visible spectrometry, X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR),
scanning electron microscope (SEM), energy dispersive x-ray spectroscopy (EDX), transmission
electron microscope (TEM), Ultraviolet–visible diffuse reflectance spectroscopy (UV-Vis DRS),
vibrating sample magnetometer (VSM) and electrochemical impedance spectroscopy (EIS).

2. Materials and methods

2.1. Chemicals

Multi-walled carbon nanotubes (+95% Pure, Outer D: 30 ~ 50 nm, Length: 10-30 μm), were
purchased from M K Impex Corp, (Mississauga, Ontario Canada). Fe(NO₃)₃.9H₂O, Ni(NO₃)₂.6H₂O,
Zn(NO₃)₂.6H₂O, Sodium Hydroxide (NaOH) and Nitric acid (HNO₃, 65%) were obtained from S D
Fine-CHEM Limited (SDFCL). All reagents were of analytical grade and were used without further
purification. Methylene Blue (MB) dye was supplied by the National Center for Leather- Khartoum,
Sudan.

2.2. Oxidation of MWCNTs

The MWCNTs were oxidized to facilitate good attachment with the other nano-materials such as
NiFe₂O₄ NPs on its outer walls [41]. For oxidation of the MWCNTs, 0.5 g of pristine MWCNTs was
sonicated in deionized water for 3 hours before adding them to a nitric acid solution (300 mL, 4
mol/liter) in an oil bath (refluxing at 110-120 °C for 7 hours). The suspension was washed several times
until the pH was neutral. Then they were dried for later usage.

2.3. Preparation of NiFe₂O₄/MWCNTs/ZnO

NiFe₂O₄/MWCNTs/ZnO hybrid nanocomposite was prepared by the hydrothermal and the co-
precipitation methods (Fig. 1). First 0.2 g of nitric acid treated MWCNTs was dispersed in 50 ml
deonized water. 1 g of Ni(NO₃)₂.6H₂O and 2 g of Fe(NO₃)₃.9H₂O were added slowly to the solution
under vigorous stirring for 10 minutes to obtain a homogenous solution. The pH of the mixture was
adjusted to13 by adding NaOH solution (6 M) drop-wise. Then the solution was subjected to stirring for
20 minutes at room temperature. After that the mixture was transferred into a 100 mL Teflon-lined
stainless steel autoclave and maintained at 210 °C in an oil bath for 5 hours. After the container is left to
cool naturally, the resulting precipitate was washed several times by deionized water. NiFe₂O₄/MWCNTs hybrid nanocomposite was then formed.
In the next stage, the as-synthesized NiFe$_2$O$_4$/MWCNTs (wet precipitate) was decorated on its outer surface by ZnO NPs using the co-precipitation method. In details, the resulting washed precipitate (NiFe$_2$O$_4$/MWCNTs) was added to a 350 ml deionized water under vigorous stirring for 10 minutes. After that 3.2 g of Zn(NO$_3$)$_2$.6H$_2$O is dissolved in the solution for also 10 minutes, and then NaOH solution (0.6 M) was added drop-wise to the solution until the precipitate appears when the color of the dark brown solution changes to be light brown, which means that zinc oxide NPs are achieved. Finally, the solution was heated at 70 °C for one hour, and then a NiFe$_2$O$_4$/MWCNTs/ZnO hybrid nanocomposite is formed. It was then washed several times and dried for later usage. Pure NiFe$_2$O$_4$ nanocomposite was synthesized by the same way as the method used for the NiFe$_2$O$_4$/MWCNTs hybrid nanocomposite except that for the NiFe$_2$O$_4$ preparation, the Teflon-lined stainless-steel autoclave was kept 3 hours only in the oil bath.

During the hydrothermal operation, in the first step, the MWCNTs act as a substrate for the growth of the spinel ferrites because of the interaction between the Ni, Fe precursors and the functional groups on the surface of the MWCNTs which covalently attach the molecules.

The mechanism for the formation of the NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposite is as follows: Firstly, the chemical treatment (oxidation) of the MWCNTs by the HNO$_3$ acid introduced a considerable carboxyl groups on the outer walls of the MWCNTs as indicated by the FTIR results. The functional groups that are negatively charged make the MWCNTs active for interaction with metal ions. With introducing functionalized MWCNTs into the solution containing the metal salts, the Ni$^{2+}$ and Fe$^{3+}$ ions are attached by electrostatic interactions to the carboxylic groups that function as nucleation sites. Then, the NaOH reacts with the metal ions that precipitate down after converting them into metal hydroxides. After heating for one hour at 100 °C, this precipitates is transformed into ferrite NPs.
2.4. Characterization of the NiFe$_2$O$_4$/MWCNTs/ZnO hybrid nanocomposite

XRD patterns of the composites were recorded using x-ray powder diffraction XRD-7000S/7000L, SHIMADZU equipped with Cu k$_{\alpha1}$ ($\lambda = 1.5406$ Å). UV–Vis diffuse reflectance spectrometer (DRS) Jasco-V-570, Japan was used to record the absorbance spectra of samples. UV–Vis spectrophotometer UV-1800, SHIMADZU was used to record the changes in the absorbance of the MB dye solution. The morphology was characterized using scanning electron microscopy (SEM) TESCAN MIRA 3 equipped with the energy dispersive spectroscopy analysis (EDS) attached part, and high-resolution transmission electron microscopy (HR-TEM) JEM-2100, JEOL, Japan. Room temperature magnetic properties were measured using a vibrating sample magnetometer (VSM) 7410-Lake Shore, USA. Fourier transform infra-red (FTIR) spectra were recorded using a SHIMADZU 8400S FTIR spectrometer. Cole–Cole semicircles were performed using electrochemical impedance spectroscopy (EIS) at room temperature in a dry nitrogen atmosphere through Novocontrol turnkey concept 40 System in the frequency range from 0.1 Hz to 20 MHz. The specimens were scanned through sandwiching between two copper electrodes (r= 0.5 cm).
2.5. Photocatalytic experiments

The activity of the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalyst was evaluated by photocatalytic decolorization of the MB dye under solar light irradiation at ambient temperature. All experiments were conducted with a constant catalyst dosage (1.0 g L$^{-1}$) and constant initial dye concentration (20 mg L$^{-1}$). Typically, 50 mg of NiFe$_2$O$_4$/MWCNTs/ZnO was added to 50 mL of MB dye solution. During the reaction, at given time intervals, 3 mL of solution was drawn and the catalyst was separated immediately by a magnet from the drawn solutions and the dye concentration was analyzed at $\lambda_{max} = 658$ nm using UV–Visible spectrophotometer. Three repeated experiments were performed (the average was taken) made the experimental data more reliable. The decolorization efficiency (η) (%) of the MB dye by the photocatalyst at time t was calculated by the equation:

$$\eta(\%) = \left(\frac{C_0 - C_t}{C_0}\right) \times 100\%$$  \hspace{1cm} (1)

taking $A_0$ and $A_t$ to represent the absorbance of the MB dye solution before and after the solar light irradiation at any time t, respectively, such that $A_t/A_0 = C_t/C_0$, where $C_0$ is the initial MB dye concentration (mg L$^{-1}$) and $C_t$ is the MB dye concentration (mg L$^{-1}$) at any time t (min). The decolorization kinetics of MB dye solution have been further investigated. The photodegradation process was fitted for the pseudo-first-order kinetic model in order to describe the corresponding experimental data [42, 43] according to the following equation:

$$\ln(C_0 / C_t) = k_{app} t$$  \hspace{1cm} (2)

where "t" is the reaction time (minutes), $k_{app}$ is the apparent reaction rate constant (min$^{-1}$).

2.5.1. Recycling experiments

In the recycling experiments, after the initial photodegradation reaction, the remaining solids were recovered by the use of an external magnet and ultrasonically washed in ethanol for 30 min to remove the MB and other by-products. Afterward, the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalyst was rinsed three times with deionized water and ethanol. The reproducibility of the catalyst was investigated by repeating the process five times at the normal pH (of the MB dye solution) and at high pH (11.55).

3. Results and discussion

3.1. Characterization of catalysts
3.1.1. Structural properties

Fig. 2 shows the XRD patterns of the pure NiFe$_2$O$_4$, MWCNTs, ZnO and NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposites. It shows that the characteristic XRD patterns of the NiFe$_2$O$_4$, MWCNTs and ZnO are present in the NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposite pattern. The characteristic peaks at 2θ = 26.08° and 43.08° are attributed to graphite structure belonging to the (002) and (100) planes of the MWCNTs [33, 44]. The diffraction peaks of the NiFe$_2$O$_4$ sample are observed at 2θ = 30.34°, 35.74°, 37.35°, 43.43°, 53.90°, 57.46° and 63.11°, which can be indexed to (220), (311), (222), (400), (422), (511) and (440) planes of the face centered cubic structure of NiFe$_2$O$_4$, respectively, space group Fd-3m, which is consistent with the JCPDS data file no. 54-0964 [45, 46]. The diffraction peaks of the ZnO sample are observed at 2θ = 31.75°, 34.45°, 36.25°, 47.6°, 56.54°, 62.86°, 66.18°, 67.95° and 69.08°, which correspond to the (100), (002), (101), (102), (110), (103), (200), (112) and (201) crystal planes of the hexagonal ZnO phase (JCPDS no. 79-0206) [24, 38, 47]. Fig. 2 shows that in the XRD pattern of the NiFe$_2$O$_4$/MWCNTs/ZnO sample no other peak related to impurities was detected which further confirms that the synthesized nanocomposite is of high purity and having good crystallinity. The average crystallite size of the nanocomposites was calculated from the most intense reflection using Debye–Scherrer's formula [48]:

$$D = \frac{0.89 \lambda}{B \cos \theta}$$

(3)

where $\lambda = 0.154056$ nm, $B$: the full peak width at half maximum value, $\theta$: the diffraction angle. The NiFe$_2$O$_4$ and the ZnO crystallite sizes were estimated to be 34.6 nm and 19.5 nm, respectively.
FTIR spectra (Fig. 3) were employed to further prove the formation of the above samples. The spectra of the raw and the oxidized MWCNTs are presented in Fig. 3(a) and the spectra of ZnO, NiFe₂O₄ and NiFe₂O₄/MWCNTs/ZnO are presented in Fig. 3(b). For the raw MWCNTs, there are no significant bands except the sharp band around 1540 cm⁻¹ corresponding to C=C stretch vibration originating from the surface of the tubes [49] and at 3452 cm⁻¹ corresponds to O–H stretching vibrations of adsorbed water molecules [12]. As a result of the oxidation process of the MWCNTs, the bands in the area 1000-1300 cm⁻¹ are attributed to C–O bending frequencies [50-52]. The band around 1730 cm⁻¹ are corresponding to C=O stretch vibration [53, 54]. Also, the bands between 2850-3000 cm⁻¹ correspond to the C–H stretching vibrations. This indicate that the –COOH group have been successfully introduced on the outer walls of the MWCNTs which make them active to attaching covalently with the decorated molecules.

Metal ions in ferrites are situated in two different sub-lattices designated as tetrahedral and octahedral according to the oxygen nearest neighbor's geometrical configuration. It has been reported that the band in the high frequency range from 650 to 550 cm⁻¹ is related to the tetrahedral A-site, while the band in the low frequency range from 450 to 385 cm⁻¹ is related to the octahedral B-site [55, 56]. In Fig. 3(b), the sharp peaks at 601 cm⁻¹ and 417 cm⁻¹ correspond to the intrinsic vibrations of tetrahedral and octahedral metal-O bounds, respectively. The peak in the area around 400–500 cm⁻¹ is assigned to
the Zn–O vibration [57], while the combination of the ferrite and the ZnO peaks appears at around 601 cm⁻¹ [24]. The weaker band in the area 1100–1300 cm⁻¹ corresponds to the vibration of the NO₃ ions which are generated during the preparation and appeared with a very less intensity [58].

![FTIR spectrum](image-url)

**Fig. 3.** FTIR spectrum of: (a) Pristine and oxidized MWCNTs, (b) ZnO, NiFe₂O₄ and NiFe₂O₄/MWCNTs/ZnO prepared nanocomposites.

### 3.1.2. Morphology and composition

The morphology of the samples was studied using SEM, EDX and TEM as shown in Figs. 4, 5 and 6. Fig. 4 (a-d) shows the pure NiFe₂O₄ and ZnO prepared NPs, and raw MWCNTs appear in the part e. The NPs sizes are estimated from the TEM images and were found to be in the nanoscale. As can be seen in Fig. 5, the surface of the MWCNTs is successfully decorated with the NiFe₂O₄ and the ZnO NPs. The NiFe₂O₄ and the ZnO NPs are bound as a hybrid and decorated the surface of the MWCNTs leading to the creation of the interaction between the NiFe₂O₄ and the ZnO NPs with each other and between them and the MWCNTs. The NiFe₂O₄ in the hybrid is much bigger than the ZnO NPs and the sizes of both pure NiFe₂O₄ and ZnO are smaller in the hybrid. The average size of the NiFe₂O₄ NPs on the surface of the MWCNTs is about 50 nm which is smaller than that of pure NiFe₂O₄ NPs (Figs. 4, and 5) indicating that the existence of MWCNTs has led to the crystallization of NiFe₂O₄ and ZnO NPs with smaller sizes. Hence, the introduction of MWCNTs as a good support will make the loaded NiFe₂O₄ and ZnO achieve a further enhancement of the charge separation and suppressing the electron–hole recombination in photocatalytic processes [13]. The elemental mapping images and EDS spectra (Fig. 6)
were also inspected and displayed. The sample contains O, Fe, Ni, Zn, C elements, further indicating that NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposite is successfully prepared.

The work in ref. [13] is the most close example to our present study where a novel NiFe$_2$O$_4$/MWCNTs hybrid nanocomposite has been synthesized via the hydrothermal method to remove the CR dye from its solutions using solar radiation time of 300 minutes reaching an efficiency of up to 90%. We can observe the formation of NiFe$_2$O$_4$ NPs in a larger size compared to the sizes formed on the surface of CNTs in this work and the morphology was similar to the mixture. That is due to the nature of the formation of the NiFe$_2$O$_4$ NPs, which are formed in large sizes compared to e.g. Fe$_3$O$_4$ ferrite which is formed in smaller sizes, thus allowing for homogeneous decoration of the entire surface of the MWCNTs.

In this work, the defects that we have seen in the morphology were due to the relatively short time applied in the MWCNTs treatment (only 7 hours). Since the treatment process (oxidation) of the pristine MWCNTs is the first essential step to the success of any functionalization process for the carbon nanotube surface, the time required for efficient processing must be longer.
Fig. 4. (a), (b) SEM and TEM images of NiFe$_2$O$_4$ nanoparticles, respectively. (c), (d) SEM and TEM images of ZnO nanoparticles, respectively, and (e) SEM image of raw MWCNTs.

Fig. 5. (a) SEM, and (b) TEM images of NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposite.
3.1.3 UV–Vis Diffuse Reflectance Spectroscopy (DRS) and Electrochemical Impedance Spectroscopy (EIS)

The optical absorption technique can be employed for an examination of optically induced transitions and can give information about energy gap ($E_g$) in crystalline materials, non-crystalline materials and the bond structure [59]. In the absorption process an electron transition from a lower to higher energy state happens via the absorption of a photon of specified energy. Hence, changes in the radiation absorbed can decide possible electron transitions. Fundamental absorption shows a surprising change in absorption and can be used in the determination of the optical band gap ($E_g$) (see equation 4).
Reflectance spectroscopy technique is closely related to the UV/Vis spectroscopy, in that both of them use visible light to excite valence electrons to empty orbitals. The difference is that in diffuse reflectance, we measure the relative change in the amount of light reflected off of a surface, whereas in UV/Vis spectroscopy we measure the relative change of transmittance of light as it passes through a solution.

UV–Vis diffuse reflectance spectroscopy (DRS) was used to determine the optical absorption properties of the samples. Fig. 7(a) gives the UV-Vis DRS spectra of the NiFe$_2$O$_4$ and the NiFe$_2$O$_4$/MWCNTs/ZnO composites. ZnO has a sharp optical-absorption edge at about 386 nm, so it absorbs UV light to a degree higher than visible light. Fig. 7(a) showed that the NiFe$_2$O$_4$ absorbs the light in the whole region (200 to 800 nm) due to its small band gap (1.64 eV) which is consistent with the previous observations [13, 33]. However, NiFe$_2$O$_4$ is rarely applied as a visible light photocatalyst alone since the electrons could not survive long in the conduction band and it will return to the valence band (h$^+$). Consequently photodegradation processes do not occurs as it should [60], but synergistic effect between NiFe$_2$O$_4$, ZnO and MWCNTs can leads to a significant enhancement in photo-activity due to the effective charge transfer from the NiFe$_2$O$_4$ to the ZnO and then to the MWCNTs and thus suppresses recombination of electron–hole pairs in the composite [33]. By extrapolating the linear portion near the commencement of absorption edge to x-axis, the optical band gap ($E_g$) of NiFe$_2$O$_4$ and NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposites were found to be 1.64 eV and 2.3 eV, respectively. The band gap of the hybrid nanocomposite was calculated as the average value obtained from the absorption spectrum (equation 4 and Fig. 7a) and the Tauc plot (equation 5 and Fig. 7c). The estimated band gaps are obtained from Fig. 7a by dividing 1240 by the intersection point of the extension line of the tangent of the curve (NiFe$_2$O$_4$ and NiFe$_2$O$_4$/MWCNTs/ZnO) and the abscissa using the equation [24]:

$$E_g = \frac{hc}{\lambda_g}$$

$$E_g (eV) = \frac{1240}{\lambda_g}$$ \hspace{1cm} (4)

where $h$ is Planck constant and $c$ is the speed of light. Results also were expressed from the plots $(a\nu h)^2$ vs. photon energy $(\nu h)$ as shown in Fig. 7(b, c) by Tauc equation [61-63]:

$$(a\nu h)^2 = A (\nu h - E_g)$$ \hspace{1cm} (5)

where $A$ is a constant that depends on the transition probability, and $\alpha$ is the absorption coefficient [64].

Compared to the known absorption curves of zinc oxide, the bias of the absorption spectra of the hybrid compound in the visible light area indicates that the combination of the NiFe$_2$O$_4$, the MWCNTs
and the ZnO has enhanced the absorption efficiency of the light. This makes the composite more effective and efficient in the photocatalytic processes to remove dyes contaminants under the sun’s radiation.

In addition to the good light response ability of the light, good charge separation was supported by electrochemical impedance spectroscopy (EIS) to further characterize the transfer of the photogenerated electron-hole pairs. As showed in (Fig. 7d), the NiFe$_2$O$_4$/MWCNTs/ZnO hybrid photocatalyst showed much smaller semicircle than the NiFe$_2$O$_4$ and the NiFe$_2$O$_4$/MWCNTs, indicating that the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalyst exhibited the lowest charge-transfer resistance. Therefore, the existence of the NiFe$_2$O$_4$ and the ZnO in the surface layer of the MWCNTs could effectively separate the photogenerated electron and photogenerated holes produced by the NiFe$_2$O$_4$ and the ZnO and subsequently, hindering the recombination process [19].

(d) Electrochemical impedance spectroscopy (EIS) curves (Cole–Cole semicircles ($M''$ vs. $M'$)) of the NiFe$_2$O$_4$, the NiFe$_2$O$_4$/MWCNTs and the NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposites at room temperature.
### 3.1.4 Magnetic properties

The magnetic properties of the NiFe$_2$O$_4$ and the NiFe$_2$O$_4$/MWCNTs/ZnO samples were performed by VSM at room temperature with an applied magnetic field up to 20 KOe. The saturation magnetization ($M_s$), remanence ($M_r$) and coercivity ($H_c$) of the samples are shown in Table I.

The hysteresis loops shown in Fig. 8 revealed that the NiFe$_2$O$_4$ and the NiFe$_2$O$_4$/MWCNTs/ZnO nanocomposites have a superparamagnetic behavior at room temperature. The saturation magnetization ($M_s$) value of the NiFe$_2$O$_4$/MWCNTs/ZnO hybrid (17.021 emu g$^{-1}$) is much lower than that of the pure NiFe$_2$O$_4$ (37.8 emu g$^{-1}$), which is ascribed to the existence of other nonmagnetic material, i.e. the MWCNTs and the ZnO [24, 38, 41]. Also, as we found before in the structural properties, the size of the NPs of nickel ferrite formed on the surface of the MWCNTs is smaller than that of the NiFe$_2$O$_4$ bare material. So, in this case, the spins on the surface of the NPs are canted and hence the magnetization is reduced [65, 66].

Mainly, the magnetic order in a spinel ferrites material such as NiFe$_2$O$_4$ is due to the super exchange interaction mechanism happening between the metal ions in the tetrahedral and the octahedral sublattices. The spinel can be of normal or inverse structure according to the distribution of the cations on the interstitial tetrahedral (A) and octahedral (B) sites [67]. In the normal structure all divalent A$^{2+}$ (trivalent B$^{3+}$) cations occupy tetrahedral (octahedral) lattice sites exclusively, while in the inverse, the trivalent B$^{3+}$ cations distributed equally across the tetrahedral (A) and octahedral (B) sites and the divalent A$^{2+}$ cations only occupy the B sites. A mixture of both structures is quantified by the inversion parameter $\lambda$. Here, $\lambda$ is the fraction of A$^{2+}$-cations occupying B sites. $\lambda = 0$ denotes a normal ($A^{2+}$B$^{3+}$O$_4$) and $\lambda = 1$ denotes a fully inverse spinel lattice ($B^{3+}$A$^{2+}$B$^{3+}$O$_4$) [67-70].

The net magnetization in the inverse spinel NiFe$_2$O$_4$ is the result of these two sub-lattices in which the Ni$^{2+}$ ions incline to occupy the B-site, and Fe$^{3+}$ ions occupy both A- and B-sites [71, 72] as the chemical composition formula [Fe$^{3+}$]Ni$^{2+}$Fe$^{3+}$O$_4$ [72]. In the bulk inverse spinel NiFe$_2$O$_4$, the distribution of the Fe$^{3+}$ ions of high magnetic moment (5 $\mu_B$) is equal on both the A- and the B-sites [68]. The magnetic moments of the Fe$^{3+}$ cations is equivalent to the antiferromagnetic conjugation between the A- and B sites, only the Ni$^{2+}$ cations is taken into account for the net magnetization of 2$\mu_B$/f.u [68].
The magnetic behavior of the NPs is determined by the structural, the magnetic and the surface properties of the individual NPs and the interactions among them. Practically, inter-particle interactions are inevitable mainly due to van der Waals forces and the interaction of magnetic dipolar of magnetic moments. By reducing the inter-particle distances in magnetic NPs, superparamagnetic relaxation, for instance, is affected remarkably [73, 74]. The mechanism can be explained in terms of spin-glass like state, spin canting and spin-disorder in the surface layers of NPs because of the broken exchange interaction, local chemical disorder and an unlike local symmetry for the surface atoms [71]. On the surface of the ferrite NPs, the spins can be in a disturbed state because of several reasons: (a) Differences in coordination of the surface cations can lead to a distribution of the net exchange fields, whether positive or negative with respect to a cations sub-lattice; (b) because an oxygen ion mediated the super exchange interaction, and if an oxygen ion is missing, the exchange bonds will be broken [75]. In magnetic NPs, the most studied finite-size effects are the superparamagnetic limit and the single domain limit [76]. The reduction of the grain size can strongly affects the magnetic properties of the materials because of the influence of the thermal energy over the ordering of the magnetic moment causing a paramagnetic relaxation phenomenon [74]. Depending on the magnetic domain theory, there is a critical size $d_s$ of single domain particles. If the particle size $D$ is larger than $d_s$, the magnetic particles are multi-domain particles and their coercivity ($H_c$) increases with the decrease of $D$. With reduced particle size to a critical diameter, the value of coercivity increases to a maximum value. When the particle size decreases furthermore below the critical size, the coercivity decreases toward zero and the particles become superparamagnetic [33, 77]. This may explain why the coercivity of the hybrid nanocomposites is slightly larger than that of the unsupported ferrite [33] as in Table I. Also, as in the table, the remanence ($M_r$) of both compounds is very small and almost equal to zero. The impermanent magnetization ($M_r=0$) after the magnetic field removal in superparamagnetic materials is an important feature for carriers in magnetic target [78].

Although the $M_s$ value of the hybrid nanocomposite is much lower than that of the NiFe$_2$O$_4$, it is still relatively high and ensures high magnetic response toward an external magnetic field. The NiFe$_2$O$_4$/MWCNTs/ZnO hybrid composite showed strong attraction with a magnet, which is important for their applications in the biological field to eliminate organic pollutants and in for an economical approach for the treatment of industrial wastewater, as the nanocomposite can be reused.
3.2. Photocatalytic activity of the NiFe$_2$O$_4$/MWCNTs/ZnO hybrid photocatalyst

The photocatalytic activity for decolorization of Methylene Blue (MB) dye (molecular formula: C$_{16}$H$_{18}$ClN$_3$S.3H$_2$O) as an example of the sun radiation driven photocatalytic activity using NiFe$_2$O$_4$/MWCNTs/ZnO hybrid nanocomposite catalyst compared with the adsorption process has been investigated (Fig. 9a). In addition, the photodegradation activity is compared with the performance of NiFe$_2$O$_4$ and ZnO under solar light irradiation for 300 minutes. Then, to describe the corresponding experimental data and to evaluate the mechanism of photocatalytic process, the pseudo-first-order kinetic model was applied to fit the data (see the correlation factors (R$^2$) of the catalysts in Fig. 9b).

With normal pH, the decolorization efficiency of the MB solution for 300 minutes under solar light irradiation using NiFe$_2$O$_4$/MWCNTs/ZnO, NiFe$_2$O$_4$ and ZnO catalysts were 73.02%, 11.48% and 43.78%, respectively, and the corresponding decolorization rate constants ($k_{app}$) were 0.00438 min$^{-1}$, 4.12857E$^{-4}$ min$^{-1}$ and 0.002 min$^{-1}$, respectively, according to the pseudo first-order kinetic model (equation 2). The NiFe$_2$O$_4$/MWCNTs/ZnO hybrid showed a photocatalytic efficiency ($\eta$) of 73.02% at a pH = 6.66 (pH of the dye solution) and 98% with pH = 11.55 at the same conditions (the same irradiation time and the same concentration of the catalyst) (Fig. 10).
Fig. 9. (a) Adsorption and photocatalytic efficiency of MB dye degradation using NiFe₂O₄/MWCNTs/ZnO photocatalyst for 300 min. (b) ln(C₀/Cₜ) versus irradiation time for MB degradation using NiFe₂O₄/MWCNTs/ZnO, ZnO, and NiFe₂O₄ nanocatalysts, where pseudo-first-order kinetic model was applied to describe corresponding experimental data. (Normal pH, catalyst concentration: 1.0 g/L, concentration of MB dye solution: 20 mg/L).

Fig. 10. (a) Photocatalytic efficiency of MB dye degradation as a function of solar light irradiation time using NiFe₂O₄/MWCNTs/ZnO nanocomposite for 300 min with different pH values (3, 6.66 (normal) and 11.55). (b) Catalyst reuse for five cycles under the same conditions at pH = 6.7 (normal) and pH = 11.6.
Obviously, from Fig. 9b, in the presence of the NiFe$_2$O$_4$, there is no significant increase of the MB degradation, and ZnO has more excellent photocatalytic efficiency compared to NiFe$_2$O$_4$.

The reaction mechanism for the MB dye photo-degradation using the ZnO, the NiFe$_2$O$_4$ and the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalysts is similar. The first step (before starting the exposure to the irradiation) begins by adsorbing the dye on the catalyst surface through stirring, which is an essential step before the photocatalytic interaction [13, 33, 38, 79] (Fig. 11). The good removal efficiency for the MB dye by the NiFe$_2$O$_4$/MWCNTs/ZnO corresponds to UV-Vis DRS results which showed a high absorption of the irradiation in the visible and ultraviolet regions. Fig. 11 illustrates the photocatalytic decolorization of the MB dye using the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalyst under solar light irradiation and illustrates the magnetic separation. In order to compare the performance of the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalyst to the other similar photocatalysts, the photocatalytic activity of other related magnetic carbon nanotubes (Mag-CNTs) and related ZnO/carbon nanotubes nanocomposites are shown in Table II.

**Fig. 11.** Diagram illustrates the photocatalytic decolorization of MB dye using NiFe₂O₄/MWCNTs/ZnO hybrid catalyst under solar light irradiation and illustrates the magnetic separation.

### 3.2.1. Reproducibility

Recycling can effectively reduce the waste of resources and environmental pollution [16, 86]. The reproducibility of the NiFe₂O₄/MWCNTs/ZnO photocatalyst for 5 cycles was displayed in Fig. 10b. It could be clearly seen that the photocatalyst could be used at least 5 cycles with a little loss of photocatalytic efficiency, indicating that it had good photochemical stability. The loss of photocatalytic efficiency after five cycles for MB dye degradation might be ascribed to the sample loss during the magnetic separation and recovery process.

### 3.2.2. Mechanism of photocatalytic decolorization process

Based on the experimental results and some previously submitted reports [2, 38] on the mechanism of the photocatalytic decolorization to remove organic pollutants, the presented mechanism can be described as follows: at first, the MB dye molecules are adsorbed on the outer surfaces of the NPs on the catalyst. By exposure to solar radiation, electrons (e⁻) in the valence band (VB) of NiFe₂O₄ and ZnO are excited to the conduction band (CB). This will simultaneously lead to generate gaps with positive charge in the VB. Due to the difference in energy bands between the nickel ferrite, the carbon
nanotubes and the ZnO, the photo-generated electrons ($e^-$) can be transferred to the ZnO and to the MWCNTs instantly. This causes charge separation and stabilization, subsequently hindering the recombination process [40, 41]. After that, the generated electrons react with $O_2$ contained in the solution to yield $O^{2-}$ ions which will further react with $H_2O$ forming $^\cdot$OH hydroxyl radical [24]. It is established that the photocatalytic reactive species are capable of attacking and degrading organic pollutants in the photocatalytic reaction [87-89].

The VB potential of the ZnO is more positive than that of the NiFe$_2$O$_4$ while the CB potential of NiFe$_2$O$_4$ is more negative than that of the ZnO. Therefore, the photo-produced electrons ($e^-$) in the NiFe$_2$O$_4$ will be transferred across the interface of the NiFe$_2$O$_4$/ZnO hybrid to the surface of ZnO [38] then to the MWCNTs. The active species included in the photocatalytic degradation reaction are photo-generated holes ($h^+$), hydroxyl radicals ($^\cdot$OH) and superoxide radical anions ($O_2^{\cdot-}$). The surface-adsorbed MB molecules were attacked by the active species (free radicals) to become simple compounds such as CO$_2$, H$_2$O and other byproducts.

For both zinc oxide and nickel ferrite in particular this low efficiency in the photocatalytic degradation is due to the recombination process of the photo-induced electron–hole pairs that happen immediately and does not allow the pairs to flow and interact with the dye solution. The high photocatalytic efficiency at the high values of the pH is due to the increase of the amount of hydroxide anions ($OH^-$) in the solution which contribute to the decolorization process and this is the same effect of other oxidizing agents such as hydrogen peroxide (H$_2$O$_2$).

According to the our control sample and as in shown in previous studies on other dyes [24], it is worth mentioning that the solar radiation alone contributes in the breakdown of the bonds in methylene blue dye with degradation efficiency up to 10% at the end of the irradiation time. This is due to the direct effect of photons of solar radiation. Just as photons directly generate electron-gap pairs by photocatalysis and then free radicals are created, photons directly break the bonds of the dye and also indirectly affect in increasing the kinetic energy of free radicals formed.
Fig. 12. Diagram of the proposed mechanism of MB dye removal by photocatalytic decolorization over NiFe$_2$O$_4$/MWCNTs/ZnO hybrid catalyst.

Based on these results, the most likely mechanism of the photocatalytic degradation is illustrated in Fig. 12 and equations 6-9. The main process is as the following:

$$\text{NiFe}_2\text{O}_4/\text{MWCNTs/ZnO} + h\nu \rightarrow \text{NiFe}_2\text{O}_4/\text{MWCNTs/ZnO} \left( e^{-}_{(\text{CB})} + h^{+}_{(\text{VB})} \right)$$  \hspace{1cm} (6)  

$$\text{O}_2 + e^{-} \rightarrow \text{O}_2^{-}$$  \hspace{1cm} (7)  

$$\text{H}_2\text{O} + h^{+} \rightarrow \text{H}^{+} + \cdot\text{OH}$$  \hspace{1cm} (8)  

$$\text{MB-NiFe}_2\text{O}_4/\text{MWCNTs/ZnO} + \text{O}_2^{-}/ h^{+}/ \cdot\text{OH} \rightarrow \text{NiFe}_2\text{O}_4/\text{MWCNTs/ZnO} + \text{H}_2\text{O} + \text{CO}_2 + \text{other byproducts}$$  \hspace{1cm} (9)  

Based on the structural, optical and magnetic properties of the NiFe$_2$O$_4$/MWCNTs/ZnO photocatalyst, it is shown that the nanocomposite possesses good performance in the removal of the dyes from solutions through the processes of absorption and photocatalysis under solar radiation. Taking into account the need to prolong the time required to oxidize the carbon nanotubes; we can avoid those defects related to morphology and ensure a homogeneous decorating process on the entire surface of the carbon nanotubes, thus increasing the photocatalytic efficiency.

As a result, the NiFe$_2$O$_4$/MWCNTs/ZnO is a novel multifunctional photocatalyst for an economic treatment of dyed wastewater with the advantages of low cost, good adsorption, high photocatalytic activity with magnetically separation possibility.
4. Conclusions

Novel multifunctional NiFe$_2$O$_4$/MWCNTs/ZnO hybrid nanocomposite was synthesized by the hydrothermal and the co-precipitation methods and used as an efficient photocatalyst with good adsorption and photocatalytic activity. The NiFe$_2$O$_4$/MWCNTs/ZnO hybrid composite exhibited enhanced photocatalytic activity compared to the NiFe$_2$O$_4$ and to the ZnO for the decolorization of MB as a model pollutant under solar light irradiation for 5 hours. High removal efficiency was obtained at relatively high values of the pH, when the catalyst concentration was 1.0 g/L and the concentration of MB dye solution was 20 mg/L. Pseudo-first-order kinetic model was applied to demonstrate the corresponding experimental data. It was found that the combination of the NiFe$_2$O$_4$, the MWCNTs and the ZnO enhances the absorption efficiency of light with band gap of 2.3 eV for the NiFe$_2$O$_4$/MWCNTs/ZnO hybrid catalyst. In the photocatalytic degradation reaction, the $^•$OH, h$^+$, O$_2$$^•$- free radicals attack the surface-adsorbed MB molecules and turn them to simple compounds such as CO$_2$, H$_2$O and other products. It was shown that the NiFe$_2$O$_4$/MWCNTs/ZnO hybrid nanocomposite is a super paramagnetic at room temperature with saturation magnetization ($M_s$) of 17.02 emu/g. The hybrid composite is of potential in the biological applications field specifically to remove organic pollutants and in economic treatment of the industrial wastewater. The decolorization efficiency of the MB solution for a duration of 300 minutes using the NiFe$_2$O$_4$/MWCNTs/ZnO, the NiFe$_2$O$_4$ and the ZnO catalysts were 73.02%, 11.48% and 43.78%, respectively, with corresponding apparent rate constant ($k_{app}$) of 0.00438 min$^{-1}$, 4.12857E$^{-4}$ min$^{-1}$ and 0.002 min$^{-1}$, respectively.
